Several astrophysical observations [1–3] provide compelling evidence for the existence of dark matter (DM), a type of matter not accounted for in the standard model (SM). To date only gravitational interactions of DM have been observed and it remains unknown if DM has a particle origin and could interact with ordinary matter via SM processes. However, many theoretical models have been proposed in which DM and SM particles interact with sufficient strength that DM may be directly produced with observable rates in high energy collisions at the CERN LHC. While the DM particles would remain undetected, they may recoil with large transverse momentum (p_T) against other detectable particles resulting in an overall visible p_T imbalance in a collision event. This type of event topology is rarely produced in SM processes and therefore enables a highly sensitive search for DM. Similar event topologies are predicted by other extensions of the SM, such as the Arkani-Hamed, Dimopoulos, and Dvali (ADD) model [4–6] of large extra spatial dimensions (EDs).

This analysis note describes a search for Higgs boson produced by vector boson fusion (VBF), decaying into invisible particles. The signature of such a final state will be two separated jets and an imbalance in \vec{p}_T due to the undetected particles. Two separated jets are the result of the hadronization of two final state quarks emerging from the VBF process.

This analysis makes use of data collected with the CMS detector in proton-proton (pp) collisions in 2017 at $\sqrt{s} = 13$ TeV, corresponding to an integrated luminosity of 41.5 fb^{-1} .

This paper describes a search for new physics resulting in final states with one or more energetic jets and an imbalance in p_T due to undetected particles. The jets are the result of the fragmentation and hadronization of quarks or gluons, which may be produced directly in the hard scattering process as initial-state radiation or as the decay products of a vector boson V (W or Z). These final states are commonly referred to as “monojet” and “mono- V ”. Several searches have been performed at the LHC using the monojet and mono- V channels [7–11]. This analysis makes use of a data sample of proton-proton (pp) collisions at $\sqrt{s} = 13$ TeV collected with the CMS detector at the LHC, corresponding to an integrated luminosity of 101.3 fb^{-1} . This sample is approximately three times larger than the one used in Ref. [12]. The analysis strategy is similar to that of previous CMS searches, and simultaneously employs event categories to target both the monojet and mono- V final states. In an improvement compared to previous searches, in this paper revised theoretical predictions and uncertainties for $\gamma + \text{jets}$, $Z + \text{jets}$, and $W + \text{jets}$ processes based on recommendations of Ref. [13] are used.

The analysis described in this note is performed using data collected in 2017 by CMS at 13 TeV and corresponds to an integrated luminosity of 41.5 fb^{-1} . The MC simulation samples for the background processes have been produced in the $\sqrt{s} = 13$ TeV campaigns. Further details are given in the following sub-sections.

The datasets listed in Tab. 1 are used to select events in the signal and the control regions, and to perform measurements on physics objects used in the analysis (e.g. trigger turn-ons).

Events for the signal region are collected using a set of dedicated triggers designed to select events with large p_T^{miss} and large H_T^{miss} based on the online particle flow (PF) algorithm. In these dedicated trigger algorithms, identified PF muons are removed from the event before the

Table 1: List of datasets used to select events in the signal and control regions. Datasets for both years correspond to the campaign, otherwise known as . For the 2017 data, the reconstruction is used for all periods. For 2018 data, the reconstruction is used for runs A to C, and the reconstruction is used for run D.

Year	Dataset name	Events selected for
both	/MET/Run201*/NANOAOD	Signal , single muon, double muon control regions
2017	/SingleElectron/Run2017*/NANOAOD	Single electron, double electron control regions
	/SinglePhoton/Run2017*/NANOAOD	Single photon control region
2018	/EGamma/Run2018*/NANOAOD	Single electron, double electron control, single photon control regions

p_T^{miss} and the H_T^{miss} objects are calculated. With this definition, the signal trigger paths can also be used to select single and double muon events for the W and Z control regions, respectively.

Electron events for the W and Z regions are selected using a single electron trigger. To ensure the trigger efficiency also for high- p_T electrons, the single electron trigger is used in combination with a single photon trigger [?]. The same photon trigger is used to select events for the photon control region.

The full list of triggers used, along with the L1 seeds and the associated primary datasets are shown in Table 2.

Simulation datasets for the background processes are listed in Table 3 and 4. There are several Standard Model processes that pose as backgrounds to the VBF H_{inv} signal, experimental signature of the final state being two jets with large rapidity separation and invariant mass, along with p_T^{miss} . These processes are as follows:

Z($\nu\nu$) + jets : This process yields the largest irreducible background in the analysis, consisting of a Z boson and 2 or more jets coming from either QCD or EWK vertices. Simulated samples for this background have been produced at leading order (LO) in QCD using the aMC@NLO generator in several bins of H_T .

W + jets : This process is the second largest source of background in this analysis, consisting of a W boson and 2 or more jets coming from either QCD or EWK vertices. The contribution of this background can be reduced by rejecting events with charged lepton candidates (electron/muon/tau). However, this process becomes irreducible in the case where the charged leptons are outside of the detector acceptance. Simulation samples for this background have been generated at LO in QCD using the aMC@NLO generator in several bins H_T .

Z($\ell\ell$) + jets : This process mimics signal-like events in the case where the leptons coming from the Z boson decay are not reconstructed. As in the case of $W \rightarrow \ell\nu$, the contribution of this background is reduced by rejecting events with charged leptons. Simulation samples for this process have been generated at LO in QCD using the aMC@NLO generator in bins of H_T .

Top: Top-quark decays (both $t\bar{t}$ and single top) also contribute background events to this analysis. In these processes, the W boson produced in a top-quark decay further decays

Table 2: HLT paths and the associated L1 seeds used in the analysis for the 2017 and 2018 datasets. The HLT paths ending in “_HT60” are backup triggers introduced to mitigate noise rate problems in 2017. Their inclusion is not strictly necessary for 2018, but is done for consistency.

leptonically, which produces genuine p_T^{miss} in the event. Next-to-leading order (NLO) tt simulation samples have been produced with the aMC@NLO generator. Single-top events have been generated with the Powheg generator at NLO.

Dibosons: Decays of diboson pairs (WW, WZ, ZZ) also constitute background processes. Typically, one of the bosons decays leptonically ($W \rightarrow \ell\nu, Z \rightarrow \nu\nu$) while the other boson decays hadronically, thus producing jets and p_T^{miss} in the final state. Simulated samples for WW, WZ and ZZ production have been generated at LO with Pythia 8.

QCD Multijet: QCD multijet events typically do not have large genuine p_T^{miss} . However, given the large cross section with which these events are produced, even a small fraction of events with jet mismeasurement results in a non-zero contribution of this process as background in the analysis. Simulated QCD samples have been generated at LO in QCD using the MadGraph generator in several bins of H_T .

The MC samples produced using MADGRAPH5_aMC@NLO, and POWHEG generators are interfaced with PYTHIA using the CP5 tune [?] for the fragmentation, hadronization, and underlying event description. In the case of the MADGRAPH5_aMC@NLO samples, jets from the matrix element calculations are matched to the parton shower description following the MLM [?] (FxFx [?]) prescription to match jets from matrix element calculations and parton shower description for LO (NLO) samples. The NNPDF 3.1 NNLO [?] parton distribution functions (PDFs) are used in all generated samples. The propagation of all final-state particles through

Table 3: Simulated datasets for the modelling of single electroweak boson backgrounds. All datasets are accessed at the NanoAOD data tier from the campaign, also known as .

the CMS detector is simulated with the GEANT 4 software [?]. The simulated events include the effects of pileup, with the multiplicity of reconstructed primary vertices matching that in data. The average number of pileup interactions per proton bunch crossing is found to be 32 for both the 2017 and 2018 data samples used in this analysis (assuming a total inelastic proton-proton cross-section).

In this section we should add description of the models, feynman diagrams, important model parameters

Table 4: Simulated datasets for the modelling of subleading background processes. All datasets are accessed at the NanoAOD data tier from the campaign, also known as .

All physics objects are used to identify signal-like events, to suppress backgrounds and to define control regions for background estimation. For the object definitions, we mostly follow the CMS POG endorsed recommendations. The physics objects and the selection requirements are described below.

In this analysis, jets are reconstructed by clustering PF candidates using the infrared and collinear safe anti- k_T algorithm [?]. Jets are clustered with a distance parameter of 0.4 and are referred to as AK4 jets. The reconstructed vertex with the largest value of summed physics-object p_T^2 is taken to be the primary pp interaction vertex. The physics objects are those returned by a jet finding algorithm [? ?] applied to all charged PF candidates associated with the vertex, plus the corresponding associated missing transverse momentum.

Jet momentum is determined as the vector sum of all particle momenta in the jet, and is found from simulation to be within 5 to 10% of the true momentum over the full p_T spectrum and detector acceptance. An offset correction is applied to jet energies to take into account the contribution from additional proton-proton interactions within the same or nearby bunch crossings (pileup). Jet energy corrections are derived from simulation, and are confirmed with *in situ* measurements of the energy balance in dijet, multijet, γ +jet, and leptonic Z+jet events [?]. The and versions of the jet energy corrections are used for the 2017 and 2018 data sets, respectively.

The AK4 jets used in this analysis are required to pass loose jet identification criteria. In addition, all the jets with p_T smaller than 50GeV must pass the medium pileup ID criteria. This additional constraint on all AK4 jets is found to improve the modeling of jet distributions, especially in the horn regions near $|\eta| = 2.9$. The effect of this requirement is demonstrated in

the sub-leading jet η distribution in Fig. 1.

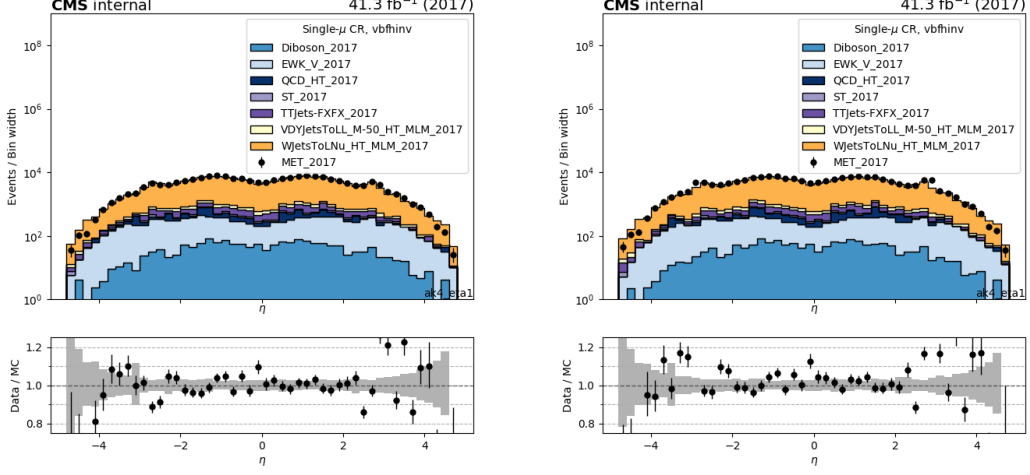

Figure 1: Subleading AK4 jet η distribution with pileup ID requirement (left) and without pileup ID requirement (right) in the single muon control region.

Lastly, to suppress the contributions due to non-collision backgrounds, the following requirements are applied on the leading AK4 jet:

- Charged hadron energy fraction > 0.1
- Neutral hadron energy fraction < 0.8

The effect of these cleaning requirements are demonstrated in the jet ϕ distribution of the signal region events in Fig. 2.

Figure 2: Leading AK4 jet ϕ distribution before and after applying the jet cleaning requirements in the signal region.

Update the b-tagging working point when the new tagging working points are defined In this analysis b jets with $p_T > 20$ GeV and $|\eta| < 2.4$ are identified using the “DeepCSV” algo-

rithm [?], adopting a working point (medium) corresponding to correctly identifying a b-jet with a probability of 80%, and misidentifying a light-flavor jet with a probability of 10%. This working point corresponds to the value of DeepCSV tagger to be greater than 0.4941. Events with identified b jets are rejected to reduce the contamination from top quark processes.

Update the V-tagging working point when the new tagging working points are defined

The vector \vec{p}_T^{miss} is defined as the imbalance in the transverse momentum of all particles that interact with the detectors. Due to momentum conservation in the plane transverse to the beam axis, \vec{p}_T^{miss} corresponds to the transverse momentum that is carried by undetected particles such as neutrinos. Practically, \vec{p}_T^{miss} is computed as the negative of the vectorial sum of transverse momenta of all PF candidates and is therefore also referred to as PF \vec{p}_T^{miss} . The magnitude of the \vec{p}_T^{miss} is referred to as p_T^{miss} .

Minimum energy thresholds in the calorimeters, inefficiencies in the tracker, nonlinearity of the response of the calorimeter for hadronic particles can lead to an over- or underestimation of p_T^{miss} . The bias on the p_T^{miss} measurement is reduced by propagating the effect of the jet energy corrections introduced in section 3.1 according to

$$\vec{p}_T^{\text{miss}}(\text{corr}) = \vec{p}_T^{\text{miss}} - \sum_{\text{jets}} (\vec{p}_{T,\text{jet}}(\text{corr}) - \vec{p}_{T,\text{jet}}), \quad (1)$$

where the “corr” refers to the scale energy corrected measurements of the related objects.

This “type-I” correction for \vec{p}_T^{miss} uses jet energy scale corrections for all corrected jets with $p_T > 15 \text{ GeV}$ that have less than 0.9 of their energy deposited in the ECAL. Furthermore, if a muon is found in a jet, its 4-momentum is subtracted from the 4-momentum of the jet when performing the correction and is added back to a corrected object.

Since signal events in this analysis contain only jets and no other reconstructed candidates, p_T^{miss} is equivalent to the total hadronic momentum in the event. For the leading backgrounds, this also corresponds to the transverse momentum of the W or Z boson. To mimic this behavior in the control regions of this analysis, the transverse momentum of the hadronic recoil \vec{U} , defined as the vectorial sum of the transverse momenta of all particles except the vector boson (or its decay products), is used. The variable is computed as

$$\vec{U} = \vec{p}_T^{\text{miss}} + \sum_{i \in \text{leptons, photons}} \vec{p}_T^i \quad (2)$$

where the sum takes into account the leptons and photons used to define the respective control region. The uncertainty of p_T^{miss} has a strong dependence on the event topology. Therefore, the uncertainty on p_T^{miss} is often factorized into its components of jets, leptons and unclustered energy. Each sub-component is then varied within its scale and resolution uncertainty. In this analysis, the largest contribution on the final p_T^{miss} uncertainty comes from the variations of the jet energy scale correction and the magnitude of the uncertainty is estimated to be 4% for the $Z(\nu\nu) + \text{jets}$ events. **Up to date?**

Anomalous high- p_T^{miss} events can appear due to various phenomena. In the ECAL, spurious deposits may appear due to particles striking sensors in the ECAL photodetectors, or from real

showers with non-collision origins such as those caused by beam halo particles. ECAL dead cells can cause real energy to be missed, again leading to a spurious imbalance. In the HCAL, spurious energy can arise due to noise in the hybrid photodiode and readout box electronics, as well as direct particle interactions with the light guides and photomultiplier tubes of the forward calorimeter. A number of filters has been developed by the POG/DPG groups to identify and suppress anomalous high p_T^{miss} events [?]. The recommended filters are listed in Tab. 5 and are applied in the analysis.

Table 5: The p_T^{miss} filters recommended by the JME POG [?]. The recommendations apply to both 2017 and 2018. Except for the bad super cluster filter (“ee badSC”), all filters are applied both in data and simulation.

Bad PF Muon Filter	Flag_BadPFMuonFilter	✓(✓)
ee badSC noise filter	Flag_eeBadScFilter	✓(×)
ECAL bad calibration filter update	Flag_ecalBadCalibFilterV2	✓(✓)

To further minimize the contribution of anomalous high- p_T^{miss} events (specifically due to spurious charged hadrons) in this analysis, a quantity based on the relative ratio of calorimetry based p_T^{miss} and PF based p_T^{miss} is employed. Examples of the distribution in single muon and single electron control regions can be found in Fig. 3, which are produced after requiring the whole set of the standard p_T^{miss} filters provided by the POG. Events satisfying $|E_{T \text{ calo}}^{\text{miss}} - E_{T \text{ PF}}^{\text{miss}}|/U < 0.5$ are selected in this analysis.

Electrons within the geometrical acceptance of $|\eta| < 2.5$ are reconstructed by associating tracks reconstructed in the silicon detector with clusters of energy in the ECAL [?]. Well-identified electron candidates are required to satisfy additional identification criteria based on the shower shape of the energy deposit in the ECAL and the consistency of the electron track with the primary vertex [?]. Electron candidates that are identified as coming from photon conversions in the detector material are removed. An isolation variable is calculated based on the sum of the energies of the PF candidates within a cone of $\Delta R < 0.3$ around the electron. The mean energy deposit in the isolation cone of the electron coming from pileup is estimated following the method described in Ref. [?] and subtracted from the isolation sum. In this note, ‘veto’ [?] electrons with a minimum p_T of 10 GeV are selected with an average efficiency of 95% and their presence is used as a condition to reject events, whereas ‘tight’ [?] electrons with a minimum p_T of 40 GeV and an average efficiency of 70% are used to select the events in the control regions. Full selection criteria are shown in Table 6.

Figure 3: The difference between calorimeter-based and PF MET relative to the hadronic recoil in data and simulated events passing the analysis selection for the single muon (left) and single electron (right) control regions. Events with values of < 0.5 are considered in the analysis.

Muons within the geometrical acceptance of $|\eta| < 2.4$ are reconstructed by combining information from the silicon tracker and the muon system [?]. The muons are required to pass set of quality criteria based on the number of spatial points measured in the tracker and in the muon system, the fit quality of the muon track and its consistency with the primary vertex of the event. Similar to electron case, the isolation requirements for muons are also based on the sum of the energies of the PF candidates, but a different cone size of a $\Delta R < 0.4$ is used. The muon isolation variable is corrected for pileup effects by subtracting half of the sum of the transverse momenta of charged particles that are inside the isolation cone and not associated with the primary vertex. In this note, “loose” [?] muons with $p_T > 10$ GeV are selected with an average efficiency of 98% and are used as a condition to reject events, whereas “tight” [?] muons with $p_T > 20$ GeV are selected with an average efficiency of 95% and are used to select events in the control samples. A full list of tight identification criteria is given here:

- Muon reconstructed as a global muon
- Muon reconstructed as a particle flow muon
- Normalized χ^2 of the global track less than 10
- At least one muon chamber hit included in the global track fit
- Muon segments in at least two muon stations
- Transverse impact parameter w.r.t. the primary vertex less than 2 mm.
- Longitudinal impact parameter w.r.t. the primary vertex less than 5 mm.
- At least one pixel hit
- Hits on at least 5 tracker layers
- $\Delta\beta$ relative isolation less than 0.15

Hadronically decaying τ leptons are required to pass identification criteria using the hadron-plus-strips algorithm [?]. The algorithm identifies a jet as an hadronically decaying tau lepton candidate if a subset of the particles assigned to the jet is consistent with the decay products of a τ candidate. Candidate τ jets are required to pass both the “DecayModeNewDMs” and “DecayMode” identifiers.

In addition, τ candidates are required to be isolated from other activity in the event. The isolation requirement is computed by summing the p_T of the charged PF candidates and PF photon candidates within an isolation cone of $\Delta R = 0.5(0.3)$, around the tau candidate direction. The charged and photon candidates associated with the tau candidate are removed from this sum and further described in Ref. [?]. The “VLoose.IsolationMVArun2v1DBnewDMwLT” isolation working point [?] is employed in this analysis for tau candidates with p_T larger than 18 GeV within $|\eta| < 2.3$.

Photon candidates are reconstructed from energy deposits in the ECAL using algorithms that constrain the clusters to the size and shape expected from a photon [?]. The identification of the candidates is based on shower-shape and isolation variables. For isolated photons, scalar sums of the p_T of PF candidates within a cone of $\Delta R < 0.3$ around the photon candidate are required to be below the bounds defined. Only the PF candidates that do not overlap with the EM shower of the candidate photon are included in the isolation sums. The photon candidates used in this analysis are required to have a minimum transverse momentum of 15 GeV and to be within $|\eta| < 2.5$ passing the ‘loose’ [?] identification criteria in. The full identification criteria is also given in Table 7.

Table 7: Loose photon identification criteria.

To be added.

Simulated signal and background samples are corrected for various effects through reweighting procedures outlined in this section.

$p_T H_T$

The performance of the $p_T^{\text{miss}} + H_T^{\text{miss}}$ triggers is measured using single muon events. The events are selected from the SingleMuon using the () trigger for 2017 (2018), and the offline muon is required to be well-identified and have p_T larger than 40 GeV. The same selection is required as for the single-muon control region used in the final fit (cf. sec. 5.2):

1. Veto on additional leptons, photons, b jets, τ_{had} candidates.
2. $\Delta\phi(jet, \vec{p}_T^{\text{miss}}) > 0.5$ for the four leading jets with $p_T > 30$ GeV.
3. $(\text{Calo } p_T^{\text{miss}} - \text{PF } p_T^{\text{miss}}) / \text{recoil} \geq 0.5$
4. $M_T(\ell, p_T^{\text{miss}}) > 160$ GeV.
5. Central AK4 jet with $p_T > 100\text{GeV}$, passing the tight jet ID.

The efficiency is calculated as a function of the hadronic recoil p_T and is shown in Fig. 4. The trigger is found to be more than 95% efficient for events with a recoil larger than 250 GeV, and more than 99% efficient for events with a recoil larger than 375 GeV. The MC-to-data scale factor is found to be within 1% of unity everywhere except for the lowest recoil bin at 250 GeV, where it is within 2%.

To investigate the stability of the measurement in single muon events, the same method is used to extract the efficiency from samples of double muon and single electron events. Again, an identical selection to the analysis control regions is used (cf. sec. 5.4 and 5.3), with the exception of requiring the leading muon p_T to be larger than 40 GeV and omitting the p_T^{miss} cut in the electron region. The H_T -binned and simulation samples are used. The resulting data-to-MC efficiency scale factors for all regions are shown in Fig. 5. For 2017, a clear trend is present: The scale factor in dimuon events is larger in absolute terms than the one from the single muon region, and the scale factor from single electron events is the smallest. The difference between all regions is within 1% relative to the single muon region. For 2018, no clear trend is observed above a recoil of 250 GeV: The scale factors from all three regions agree within the available statistical precision. Finally, the scale factors obtained from the single muon region are used to reweight the simulation. The difference to the other regions is taken into account by assigning an overall 1% uncertainty.

Figure 4: MET trigger turn-on curve measured in single muon events as a function of hadronic recoil p_T in the 2017 and 2018 datasets and H_T -binned simulation samples. The vertical blue line indicates a recoil value of 250 GeV, which is the requirement used in the analysis selection. The bottom panel shows the MC-to-data scale factor, with the blue horizontal lines indicating deviations of 1% and 2% from unity, respectively.

The photon trigger efficiency is measured using events from the JetHT dataset collected with the trigger, which was fully unscaled in 2017 and 2018¹. Events are selected in the same way as for the photon analysis control region (cf. sec. 5.6), except for the photon p_T , recoil and trigger requirements. The trigger efficiency ϵ is then determined as:

¹The other, prescaled paths yield lower statistical precision.

Figure 5: MC-to-data efficiency scale factors measured single muon events ('1m'), dimuon events ('2m') and single electron events ('1e'). For the single-lepton regions, the H_T -binned are used, and the H_T -binned samples are used for the dimuon region. The bottom panel shows the ratio of the scale factors obtained from each individual region to the scale factor obtained from the single muon region. The vertical blue line indicates a recoil value of 250 GeV, which is the requirement used in the analysis selection, while the horizontal lines indicate deviations of $\pm 1\%$ from unity.

$$\epsilon() = \frac{\text{Offline selection \&\& \&\&}}{\text{Offline selection \&\& \&\&}}$$

The resulting efficiency in data and H_T -binned simulation is shown in Fig. 6. The trigger efficiency in data is larger than 95% for a photon p_T of larger than 215 GeV, and larger than 99% for photon p_T larger than 400 GeV. Between 250 and 400 GeV, there is a slight inefficiency amounting to approximately 1% at the most, with a larger amplitude in 2017 than in 2018. In both years, the turn-on behavior is almost immediate in simulated events, resulting in an MC-to-data scale factor almost entirely driven by the efficiency in data. The scale factor is within 1% of unity for all bins except the lowest 2017 bin at 215 GeV, where it deviates from unity by about 4%.

Based on these results, the offline p_T cut for the photon in the photon control region is chosen to be 215 GeV.

We also need to add information about the single electron trigger efficiencies

The pileup (PU) conditions in the simulated samples are not identical to the ones observed measured in data, and a reweighting is applied to remove the difference. The reweighting is performed by matching the true pileup distribution of each simulated sample with the pileup distribution in data, obtained through the pileupCalc tool assuming a minimum bias cross

Figure 6: Efficiency of the trigger in data (black) and H_T -binned simulation (red) for 2017 (left) and 2018 (right) as a function of photon p_T . The bottom panel shows the MC-to-data efficiency scale factor. The blue vertical line indicates a photon p_T of 215 GeV, which is the requirement used in the analysis selection.

section of $69.2 \pm 4.6\%$ mb, following the recommendations in in Ref. [?]. The true pileup distributions in data and simulation are shown in Fig. 7. The distribution of the number of reconstructed vertices for $W \rightarrow \mu\nu$ events before and after PU reweighting is shown in Fig. 8. In this variable, the PU reweighting method leads to a worse overall agreement between data and simulation. To check this behavior, the distribution of the event energy density ρ is shown in Fig. 8, again before and after PU reweighting. Here, the agreement before PU reweighting is worse than in the primary vertex distribution and the PU reweighting clearly improves the agreement.

Data-to-simulation scale factors are applied to events in the control regions to account for differences in the reconstruction, identification and isolation of leptons between data and simulation. These data-to-MC scale factors are derived from the efficiencies that are measured for the electron and muon selections in bins of p_T and η in both data and simulation. These scale factors are provided by the relevant POGs.

The reconstruction scale factors for electrons are shown in Fig. 10. The corresponding identification scale factors for veto and tight electrons are shown in Fig. 11, and include the effect of the isolation efficiency.

The identification scale factors for muons are shown in Fig. 12. Here, isolation scale factors are applied separately and are shown in Fig. ???. The corresponding corrections for muons are deemed negligible [?].

The scale factors for id and isolation for tight muons are shown in Fig. ??.

Figure 7: Distribution of the true number of PU events in data and simulation for 2017 (left) and 2018 (right). The distributions for data are extracted assuming a minimum bias cross section of 69.2 mb.

This analysis uses the ratios of the recoil distributions in signal and control regions to constrain the final background estimate in a partially data driven way. As signal and control regions both have large statistical power, precise predictions of these ratios are necessary. To achieve this goal, the LO simulation samples for the samples W, DY and photon backgrounds are reweighted using higher-order corrections separately corresponding to NLO QCD, NLO EW and NNLO QCD terms.

All theory-based corrections of the W, DY and photon backgrounds are parametrized as a function of the generator-level p_T of the respective boson $p_{T,V}$. For each simulated event, this quantity is calculated as follows. For DY and W samples, generator-level dilepton candidates are built from:

1. “dressed” final-state electrons and muons. Lepton dressing means to collect all photons radiated off the lepton within a cone of $\Delta R < 0.1$ and adding their four-momenta back to the lepton four-momentum. This procedure is meant to undo the effect of final state photon radiation, which would otherwise distort the value of the reconstructed boson four-momentum. This effect is especially relevant as electrons and muons follow different radiation patterns. Lepton dressing is performed in central NanoAOD production following the procedure used in the RIVET software.
2. τ leptons with generator status 2. As τ leptons are unstable, they are not present as final state particles (status 1) in the generator record. The τ lepton before its decay has status 2.
3. neutrinos with generator status 1.

Figure 8: Distribution of the number of vertices in $W \rightarrow \mu\nu$ events in data and simulation before pileup re-weighting (left) and after pileup reweighting (right). The Monte Carlo is normalized to the luminosity of 41.53 and 59.7 fb⁻¹, respectively for 2017 and 2018.

The dilepton candidates are checked for flavour consistency with the desired boson candidate. If multiple candidates are found in an event, the one with the highest invariant mass is used.

For photon events, the generator photon with highest p_T and status 1 is used.

Scale factors corresponding to NLO EW corrections are obtained from Ref. [?] and applied as a function of the generator-level boson p_T . The scale factors are shown in Fig. 15.

Figure 9: Distribution of the event energy density ρ in $W \rightarrow \mu\nu$ events in data and simulation before pileup re-weighting (left) and after pileup reweighting (right). The Monte Carlo is normalized to the luminosity of 41.53 and 59.7 fb⁻¹, respectively for 2017 and 2018.

Scale factors corresponding to NLO QCD corrections for W and Z production are obtained from central CMS samples produced in the “Fall17” campaign, in which large LO and NLO samples are available. Both samples are generated using . The LO samples are identical to the ones used in in the analysis, and are generated with up to four partons in the matrix element. The NLO samples are generated with up to two additional partons in the matrix element calculation. Further jet multiplicities are handled by the parton shower, which in both cases is performed using with tune .

The scale factors are derived by obtaining the generator-level boson p_T distribution in both samples, normalizing the distributions to their respective cross sections, and then dividing

Figure 10: Scale factors for the reconstruction efficiency of electrons starting from a super cluster for 2017 (left) and 2018(right)

them as $SF = NLO / LO$. Identical selection criteria are applied to both samples based on the generator-level boson and generator-level AK4 jets, which are clustered using all visible generator particles with status 1. The requirements are:

1. The leading jet must have $p_T > 100$ GeV and $|\eta| < 2.4$.
2. The difference in the azimuthal angle ($\Delta\phi$) between the boson and the four leading jets in the event is required to be larger than 0.5. Only jets with $|\eta| < 2.4$ and $p_T > 30$ GeV are considered.

Compared to an inclusive derivation of the SF, the inclusion of the selection criteria leads to an approximately constant increase in the SF of about 2%.

The resulting SFs are shown in Fig. 14 for DY and W production. To protect the outcome of the reweighting procedure from binning effects, the binned scale factor is interpolated using a falling exponential function:

$$SF = a \times \exp(-b \times p_T) + c, \quad (3)$$

where p_T is the boson transverse momentum and a , b and c are determined by a fit to the scale factor histogram. The resulting values of the fit parameters, as well as the resulting interpolated shape are also shown in Fig. 14. A comparison of the agreement of data and simulation between the reweighted LO samples and the NLO samples is shown in Appendix ??, where good agreement between the two methods is observed.

Figure 11: Scale factors for tight (left) and veto (right) electrons are shown for 2017 (top) and 2018 (bottom). The scale factors are provided in bins of electron p_T and η .

Signal region events are selected using triggers with thresholds of 120 GeV on both $p_{T,\text{trig}}^{\text{miss}}$ and $H_{T,\text{trig}}^{\text{miss}}$. The $p_{T,\text{trig}}^{\text{miss}}$ corresponds to the magnitude of the vector \vec{p}_T sum of all the PF candidates reconstructed at the trigger level, while the $H_{T,\text{trig}}^{\text{miss}}$ is computed as the magnitude of the vector \vec{p}_T sum of jets with $p_T > 20 \text{ GeV}$ and $|\eta| < 5.0$ reconstructed at the trigger level. The energy fraction attributed to neutral hadrons in these jets is required to be smaller than 0.9. This requirement suppresses anomalous events with jets originating from detector noise. To be able to use the same triggers for selecting events in the muon control samples used for background

Figure 12: Scale factors for tight (left) and veto (right) muon identification are shown for 2017 (top) and 2018 (bottom). The scale factors are provided in bins of electron p_T and η .

prediction, muon candidates are not included in the $p_{T,\text{trig}}^{\text{miss}}$ nor $H_{T,\text{trig}}^{\text{miss}}$ computation. The trigger efficiency is measured to be 96% for events passing the analysis selection for $p_T^{\text{miss}} > 250$ GeV and becomes more than 99% efficient for events with $p_T^{\text{miss}} > 350$ GeV.

Candidate events are required to have $p_T^{\text{miss}} > 250$ GeV. The leading AK4 jet in the signal event is required to have $p_T > 80$ GeV and $|\eta| < 4.7$, and the subleading AK4 jet is required to have $p_T > 40$ GeV and $|\eta| < 4.7$. In addition, if the leading jet is within the tracker range, $|\eta| < 2.5$, it is required to have at least 10% of its energy coming from charged particles and less than 80 % of its energy attributed to neutral hadrons, as discussed in section 3. This selection helps to remove events originating from beam-induced backgrounds. In addition, the analysis employs various event filters to reduce events with large misreconstructed p_T^{miss} [?] originating from noncollision backgrounds.

Figure 13: Scale factors for tight (left) and veto (right) muon isolation are shown for 2017 (top) and 2018 (bottom). The scale factors are provided in bins of electron p_T and η .

For the VBF signal events, two leading jets in opposite hemispheres are expected, with large dijet mass. Furthermore, these jets are expected to have large rapidity separation and small azimuthal separation. Therefore, this analysis employs several requirements on M_{jj} , $\Delta\eta_{jj}$ and $\Delta\phi_{jj}$, which can be found in Table 1.

The main background processes in this search are the $Z(\nu\nu) + \text{jets}$ and $W(\ell\nu) + \text{jets}$ processes. The $Z(\nu\nu) + \text{jets}$ process is an irreducible background and constitutes the largest background in the search. In contrast, the background from $W(\ell\nu) + \text{jets}$ is suppressed by imposing a veto on events containing one or more loose muons or electrons with $p_T > 10$ GeV, or hadronically decaying τ leptons with $p_T > 18$ GeV. Events that contain a loose, isolated photon with $p_T > 15$ GeV and $|\eta| < 2.5$ are also rejected. This helps to suppress electroweak (EW) backgrounds in which a photon is radiated from the initial state. To reduce the contamination from top quark backgrounds, events are rejected if they contain a b tagged jet with $p_T > 20$ GeV and $|\eta| < 2.4$. These jets are identified using the DeepCSV algorithm [??], adopting the “medium”

Figure 14: QCD NLO scale factors for the DY (left) and W processes (right) after applying a monojet-like selection on generator level. In the top panel, the blue markers show the NLO SF derived from the simulated samples. The orange line shows a fit function used to interpolate the SF. The functional form and resulting parameters are given in the figure. In the bottom panel, the blue markers show the ratio of the histogram to the fit result in each bin.

Figure 15: EW NLO scale factors for DY, W and photon production as a function of $p_{T,V}$.

working point, which corresponds to correctly identifying a jet originating from a bottom quark with a probability of 80% and misidentifying a jet originating from a charm quark (light-flavor jet) with a probability of 12 (2)%. Lastly, QCD multijet background with E_T^{miss} arising from mismeasurements of the jet momenta is suppressed by requiring the minimum azimuthal angle between the \vec{p}_T^{miss} direction and each of the first four leading jets with p_T greater than 30 GeV and $|\eta| < 2.4$ to be larger than 0.5 radians.

The selection requirements for this analysis are summarized in Table 8.

The N -subjettiness variable τ_N [?] is also employed to further isolate jets arising from hadronic decays of W or Z bosons. This observable measures the distribution of jet constituents relative

to candidate subjet axes in order to quantify how well the jet can be divided into N subjets. Therefore, the ratio of the ‘2-subjettiness’ to the ‘1-subjettiness’ (τ_2/τ_1) has excellent capability for distinguishing jets originating from boosted vector bosons from jets originating from light quarks and gluons. The pruned jet mass and N -subjettiness requirements, whose use if referred to as V tagging, result in a 70% efficiency for tagging jets originating from V bosons and a 5% probability of misidentifying a jet as a V jet. Events that do not qualify for the mono-V category are assigned to the monojet category.

Table 8: Summary of the common selection requirements

Variable	Selection	Target background
Muon (electron) veto	$p_T > 10 \text{ GeV}, \eta < 2.4(2.5)$	$Z(\ell\ell) + \text{jets}, W(\ell\nu) + \text{jets}$
τ lepton veto	$p_T > 18 \text{ GeV}, \eta < 2.3$	$Z(\ell\ell) + \text{jets}, W(\ell\nu) + \text{jets}$
Photon veto	$p_T > 15 \text{ GeV}, \eta < 2.5$	$\gamma + \text{jets}$
Bottom jet veto	DeepCSV medium $< 0.4941/0.4184$ (2017 / 2018) for all jets with $p_T > 20 \text{ GeV}, \eta < 2.4$	Top quark
p_T^{miss}	$> 250 \text{ GeV}$	QCD, top quark, $Z(\ell\ell) + \text{jets}$
$\Delta\phi(\vec{p}_T^{\text{jet}}, \vec{p}_T^{\text{miss}})$	$> 0.5 \text{ radians}$	QCD
Leading AK4 jet p_T and η	$> 80 \text{ GeV}$ and $ \eta < 4.7$	All
Subleading AK4 jet p_T and η	$> 40 \text{ GeV}$ and $ \eta < 4.7$	All
M_{jj}	$> 200 \text{ GeV}$	$\Delta\eta_{jj}$
< 1.5 height		$> 1.0 \Delta\phi_{jj}$

Fig. 16, 17, 18, 19, shows the distribution of the E_T^{miss} , the number of jets, p_T and η distribution of the leading AK4 jet for events in the monojet and mono-V signal categories respectively for 2017 and 2018 datasets.

Figure 18: Comparison between data and monte carlo simulation in the monojet signal region for the recoil distribution, the AK4 jet multiplicity distribution, p_T and η distribution of the leading AK4 jet in 2017 dataset.

Figure 19: Comparison between data and monte carlo simulation in the monojet signal region for the recoil distribution, the AK4 jet multiplicity distribution, p_T and η distribution of the leading AK4 jet in 2017 dataset.

Single-muon control sample events are selected using full signal region criteria of VBF selection with the exception of the muon veto. The p_T^{miss} requirement is replacement an identical requirement on the hadronic recoil, which is defined as the sum of \vec{p}_T^{miss} and the muon \vec{p}_T , and thus corresponds to the distribution of the W p_T . In the single-muon control sample, exactly one tightly identified, isolated muon with $p_T > 20$ GeV is required. No additional loose muons or electrons with $p_T > 10$ GeV are allowed. In addition, the transverse mass of the muon- \vec{p}_T^{miss} system is required to be smaller than than 160 GeV. The transverse mass (M_T) is computed as $M_T = \sqrt{2E_T^{\text{miss}}p_T^\mu(1 - \cos\Delta\phi)}$, where p_T^μ is the p_T of the muon, and $\Delta\phi$ is the angle between \vec{p}_T^μ and \vec{p}_T^{miss} .

Figs. 20 and 22 show the distributions of the recoil, the number of jets, and the p_T and η distribution of the leading AK4 jet for events in the single-muon control sample for the VBF category in 2017 and 2018 datasets, respectively. Figs. 21 and 23 show the distributions of the leading muon p_T and η , as well as the muon- p_T^{miss} transverse mass, again for 2017 and 2018, respectively.

DRAFT

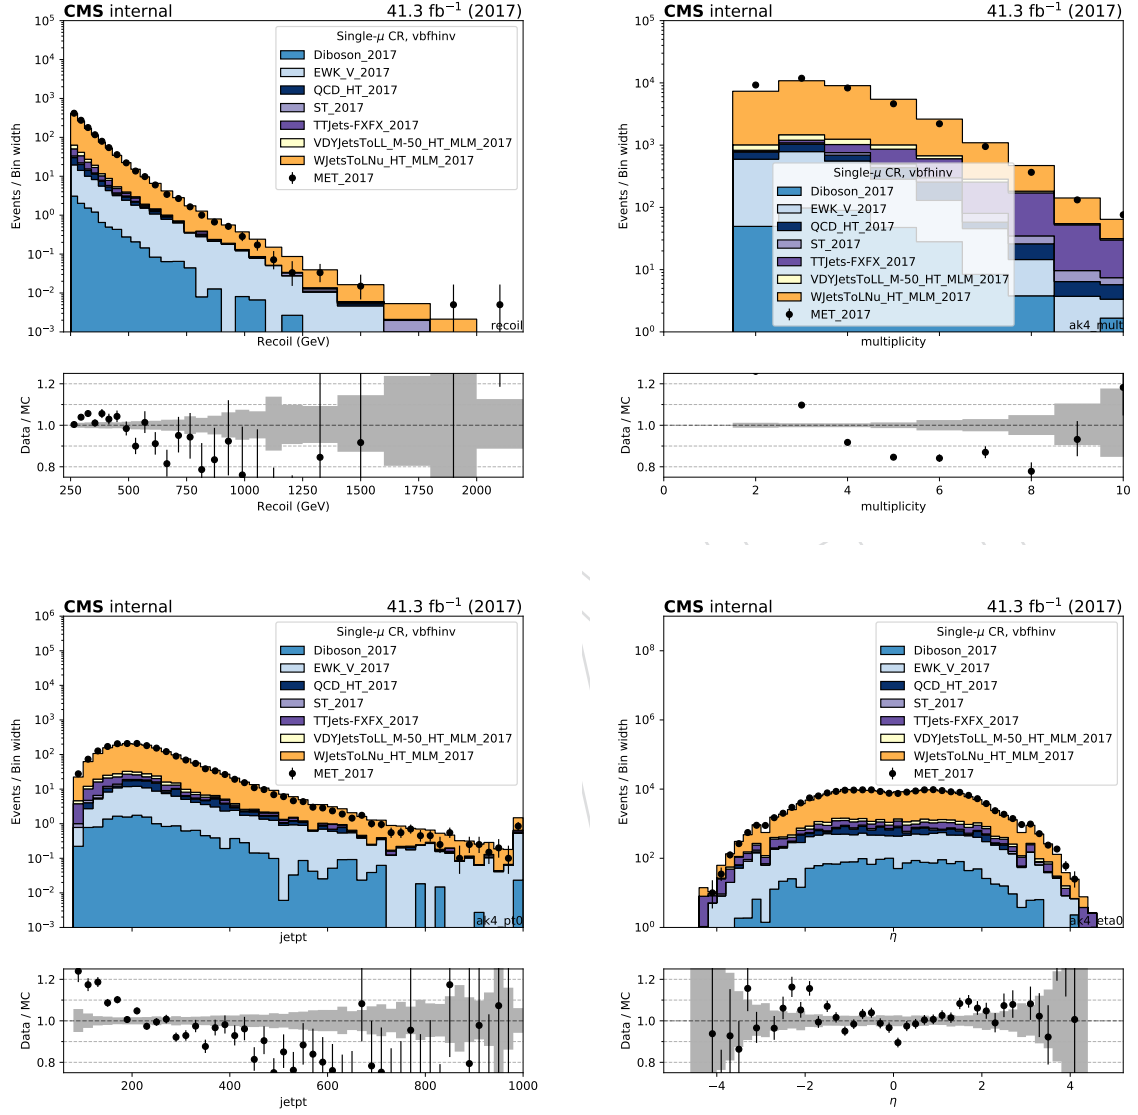

Figure 20: Comparison between 2017 data and Monte Carlo simulation in the single muon control sample for the recoil distribution, the AK4 jet multiplicity distribution, p_T and η distribution of the leading AK4 jet with the VBF selection.

Figure 21: Comparison between 2017 data and Monte Carlo simulation in the single muon control sample for the p_T and η of the leading muon and the transverse mass distribution with the VBF selection.

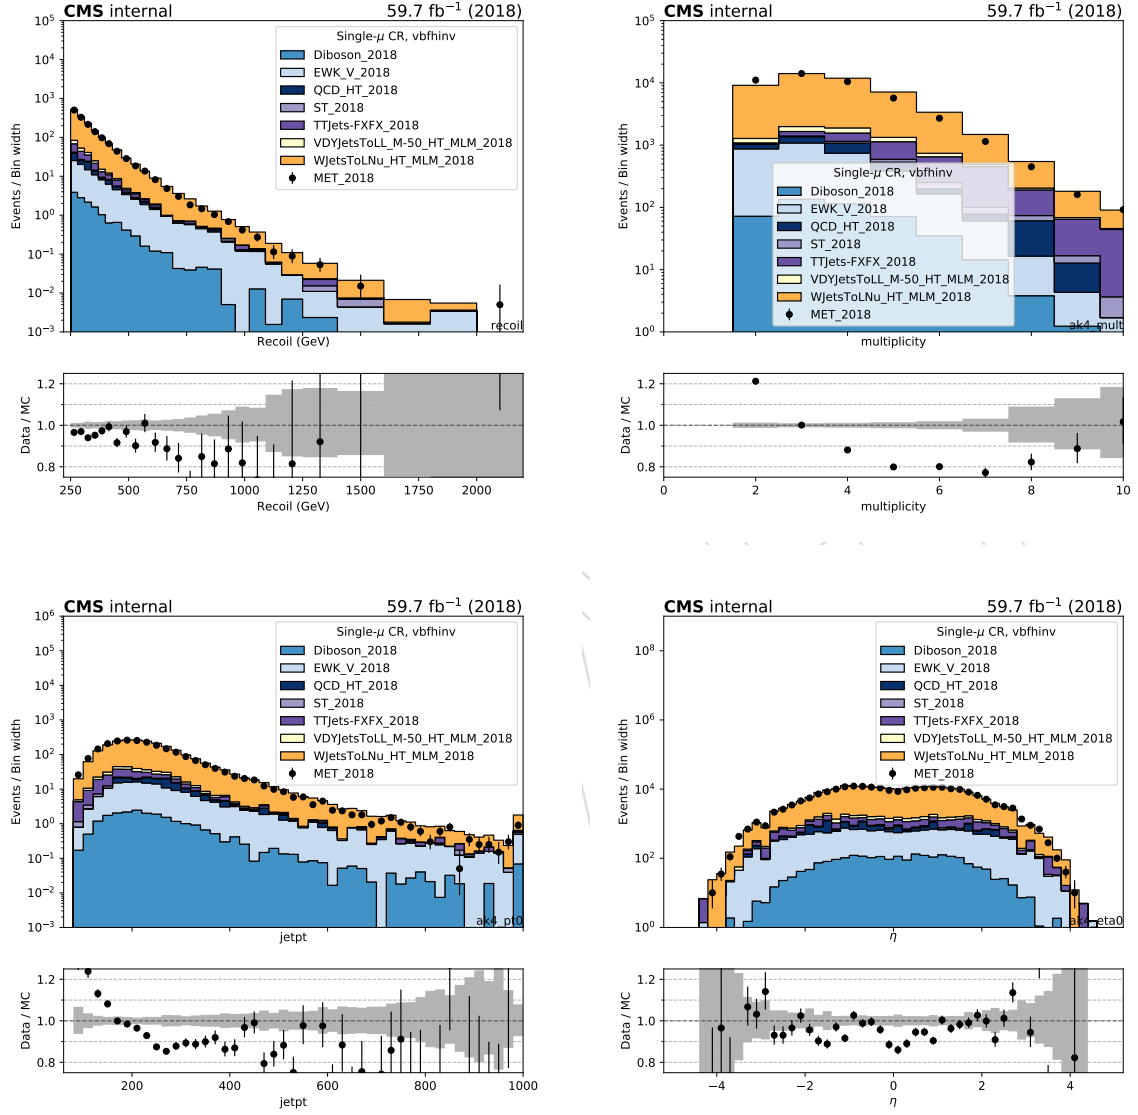

Figure 22: Comparison between 2018 data and Monte Carlo simulation in the single muon control sample for the recoil distribution, the AK4 jet multiplicity distribution, p_T and η distribution of the leading AK4 jet with the VBF selection.

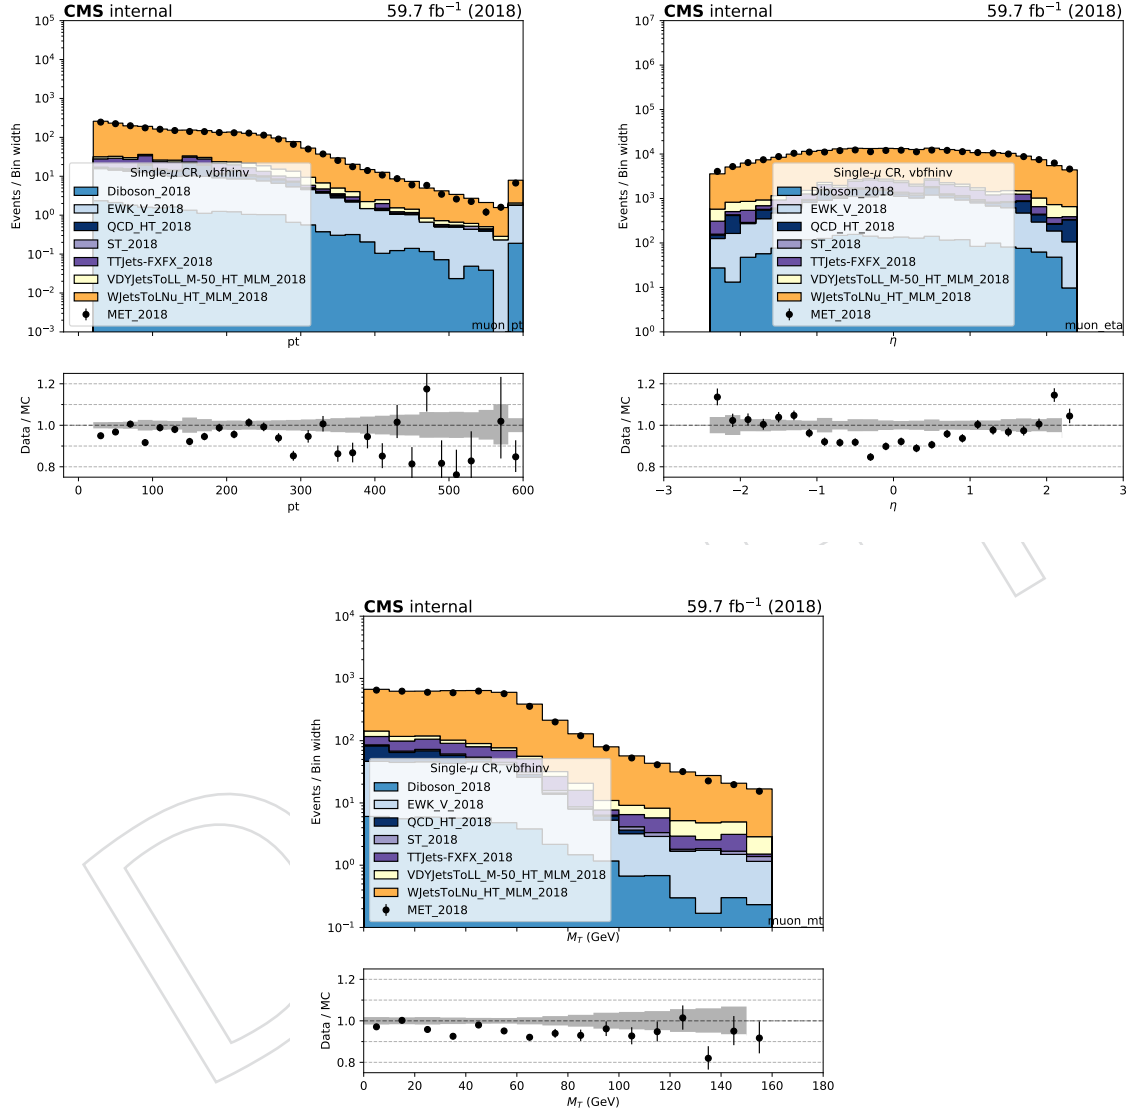

Figure 23: Comparison between 2018 data and Monte Carlo simulation in the single muon control sample for the p_T and η of the leading muon and the transverse mass distribution with the VBF selection.

Events for the single-electron control sample are collected with the single-electron and photon triggers described in Sec. 2. The p_T^{miss} requirement is replaced with an identical requirement on the hadronic recoil, which is defined as the sum of \vec{p}_T^{miss} and the electron \vec{p}_T , and thus corresponds to the distribution of the W p_T . The events in the single-electron control sample are required to contain exactly one tightly identified and isolated electron with $p_T > 40$ GeV. In addition, the contamination from QCD multijet events in this control sample is suppressed by requiring $E_T^{\text{miss}} > 50$ GeV and $M_T < 160$ GeV.

Figs. 24 and 26 show the distributions of the recoil, the number of jets, and the p_T and η distribution of the leading AK4 jet for events in the single-electron control sample for the VBF category in 2017 and 2018 datasets, respectively. Figs. 25 and 27 show the distributions of the leading electron p_T and η , as well as the electron- p_T^{miss} transverse mass, again for 2017 and 2018, respectively.

DRAFT

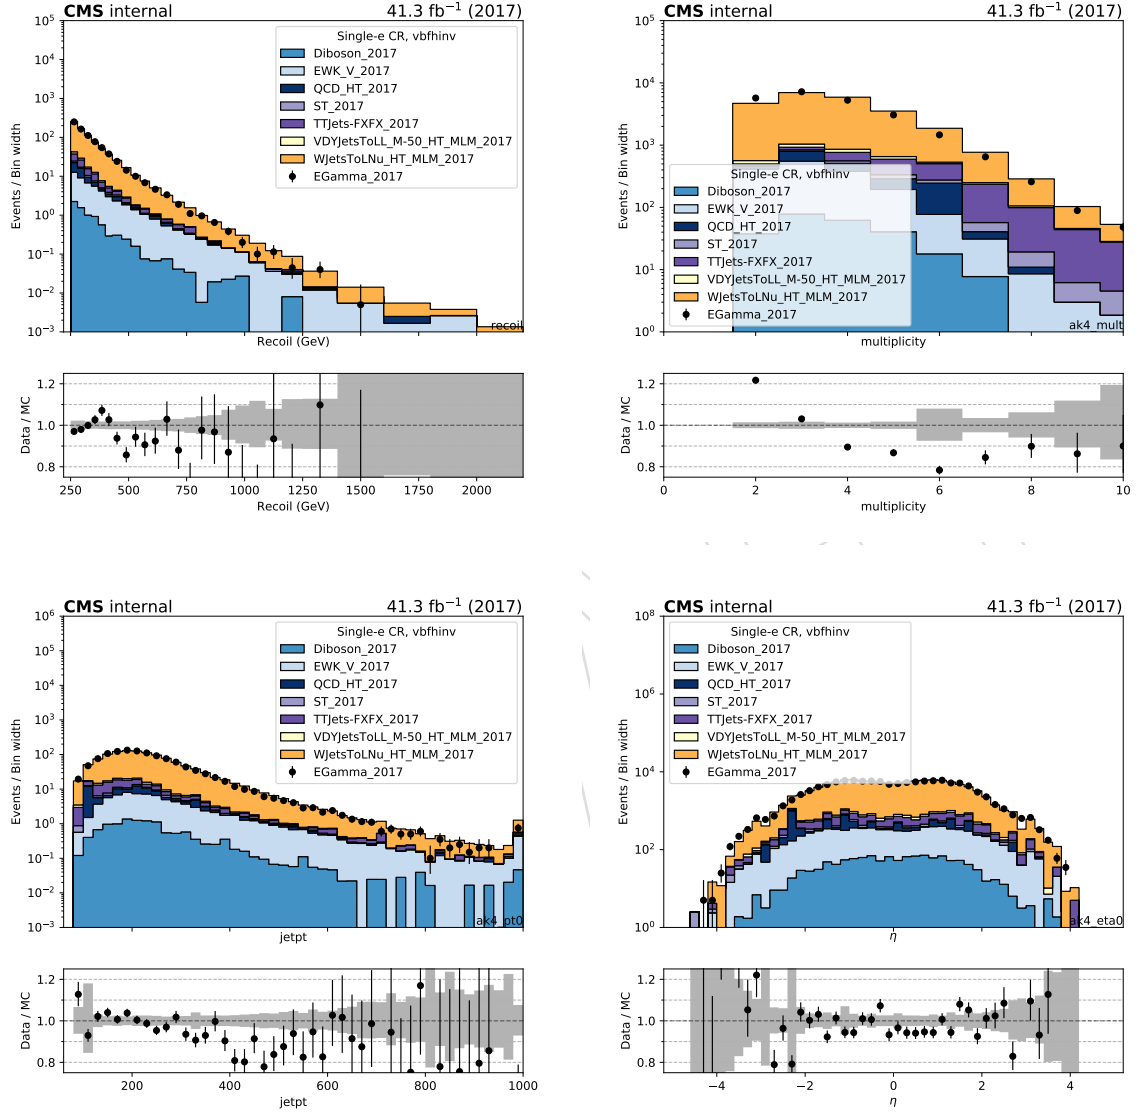

Figure 24: Comparison between 2017 data and Monte Carlo simulation in the single electron control sample for the recoil distribution, the AK4 jet multiplicity distribution, p_T and η distribution of the leading AK4 jet with the VBF selection.

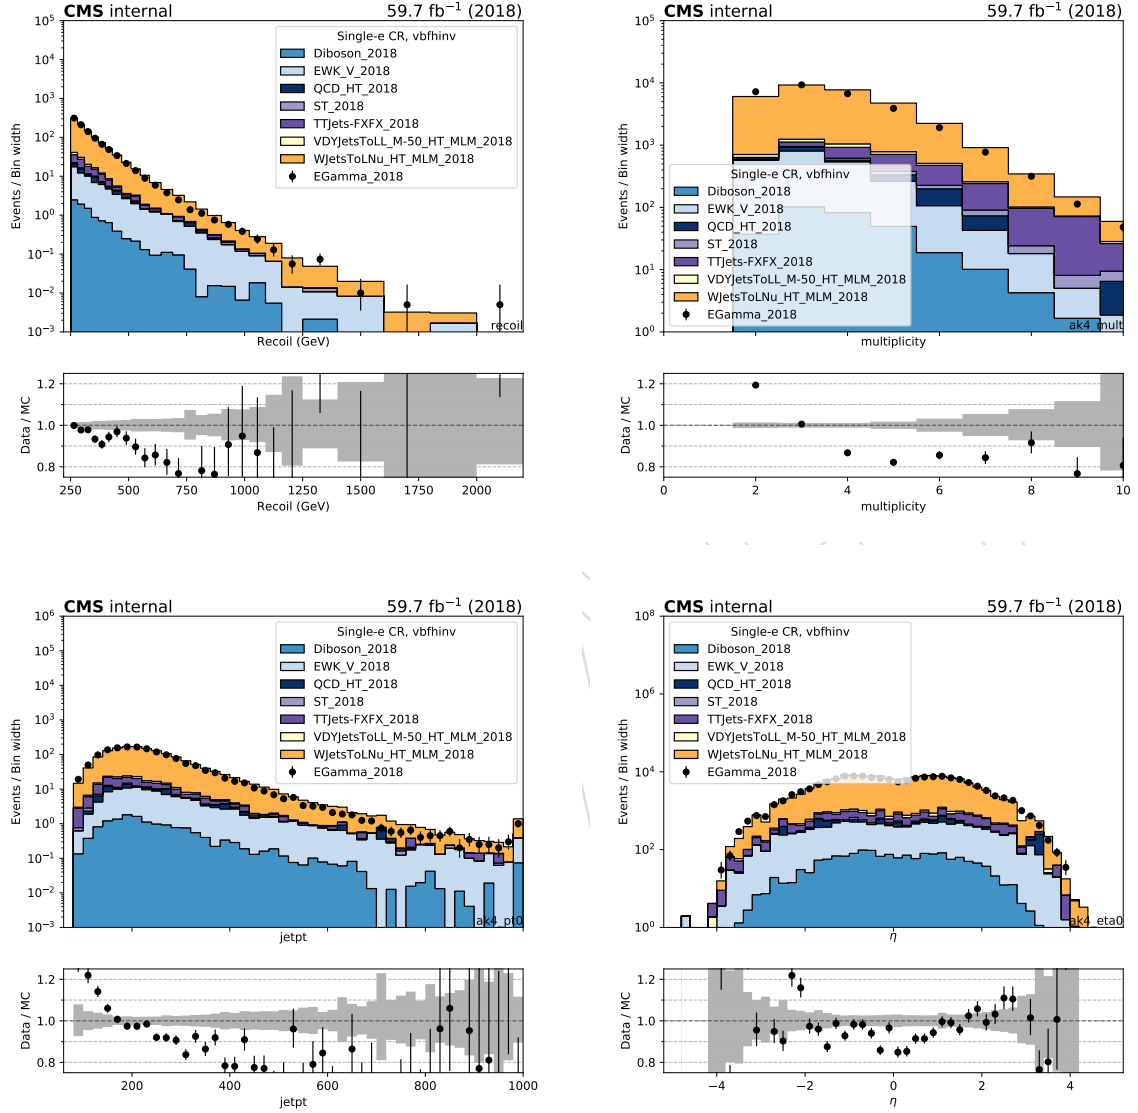

Figure 26: Comparison between 2018 data and Monte Carlo simulation in the single electron control sample for the recoil distribution, the AK4 jet multiplicity distribution, p_T and η distribution of the leading AK4 jet with the VBF selection.

Figure 27: Comparison between 2018 data and Monte Carlo simulation in the single electron control sample for the p_T and η of the leading electron and the dilepton mass distribution with the VBF selection.

Double-muon control sample events are selected using full signal region criteria of VBF category with the exception of the muon veto. In the double-muon control sample, events are selected requiring leading (subleading) muon p_T greater than 20 (10) GeV and an invariant mass in the range 60 to 120 GeV, compatible with a Z boson decay. At least one of the two muons is required to pass the tight candidate definition. Events are rejected if there is an additional loose muon or electron with $p_T > 10$ GeV. The SR p_T^{miss} requirement is replacement an identical requirement on the hadronic recoil, which is defined as the sum of \vec{p}_T^{miss} and the muon \vec{p}_T , and thus corresponds to the distribution of the Z p_T smeared with the p_T^{miss} resolution.

Figs. 28 and 30 shows the distributions of the recoil, the number of jets, and the p_T and η distribution of the leading AK4 jet for events in the double-muon control sample for the VBF category in 2017 and 2018 datasets, respectively. Figs. 29 and 31 show the distributions of the leading muon p_T and η , as well as the dimuon mass and p_T , again for 2017 and 2018, respectively.

DRAFT

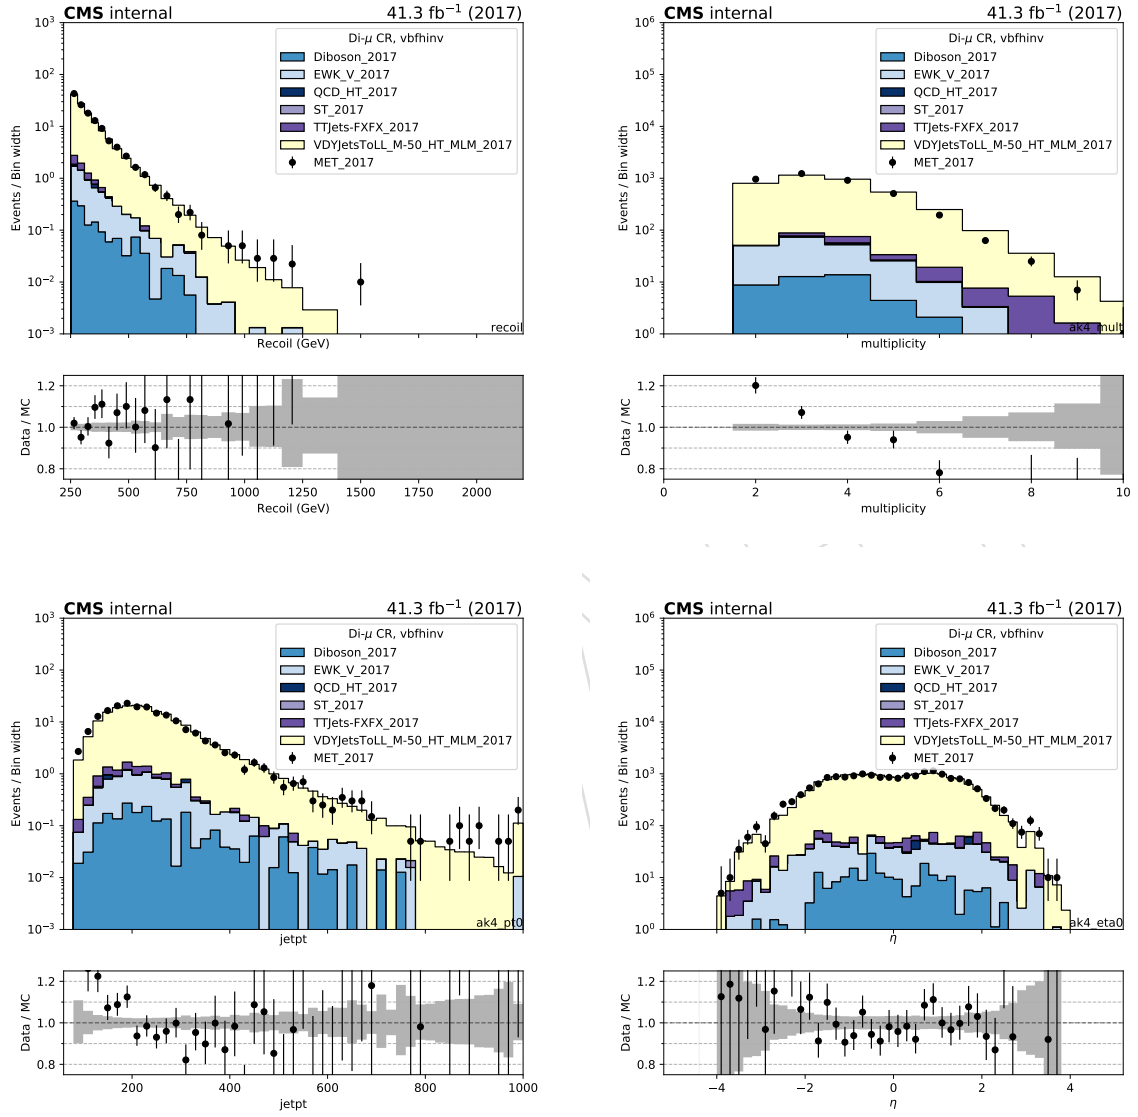

Figure 28: Comparison between 2017 data and Monte Carlo simulation in the double muon control sample for the recoil distribution, the AK4 jet multiplicity distribution, p_T and η distribution of the leading AK4 jet with the VBF selection.

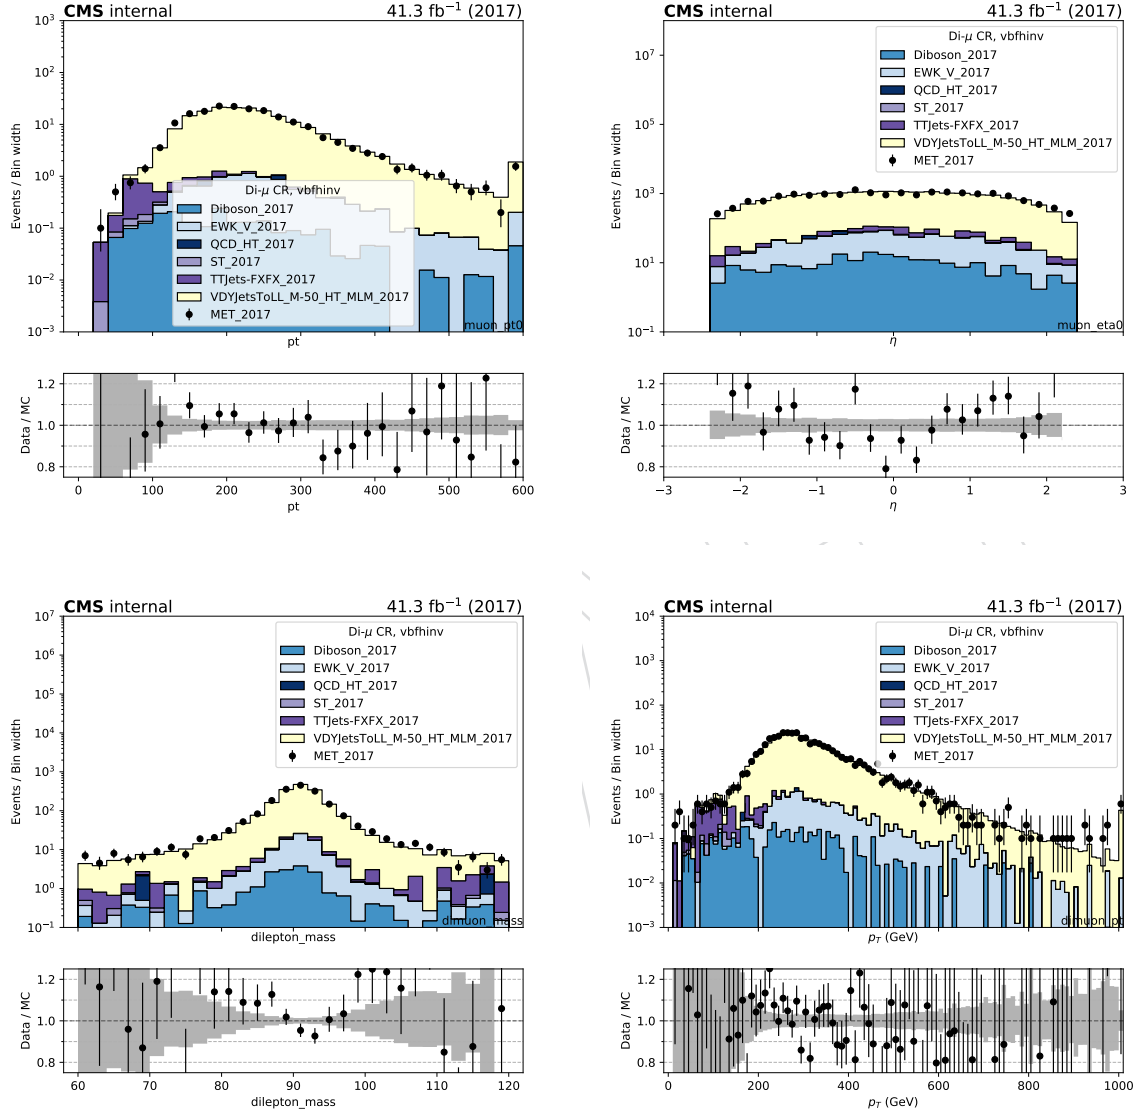

Figure 29: Comparison between 2017 data and Monte Carlo simulation in the double muon control sample for the p_T and η of the leading muon and the transverse mass and p_T of the dimuon candidate with the VBF selection.

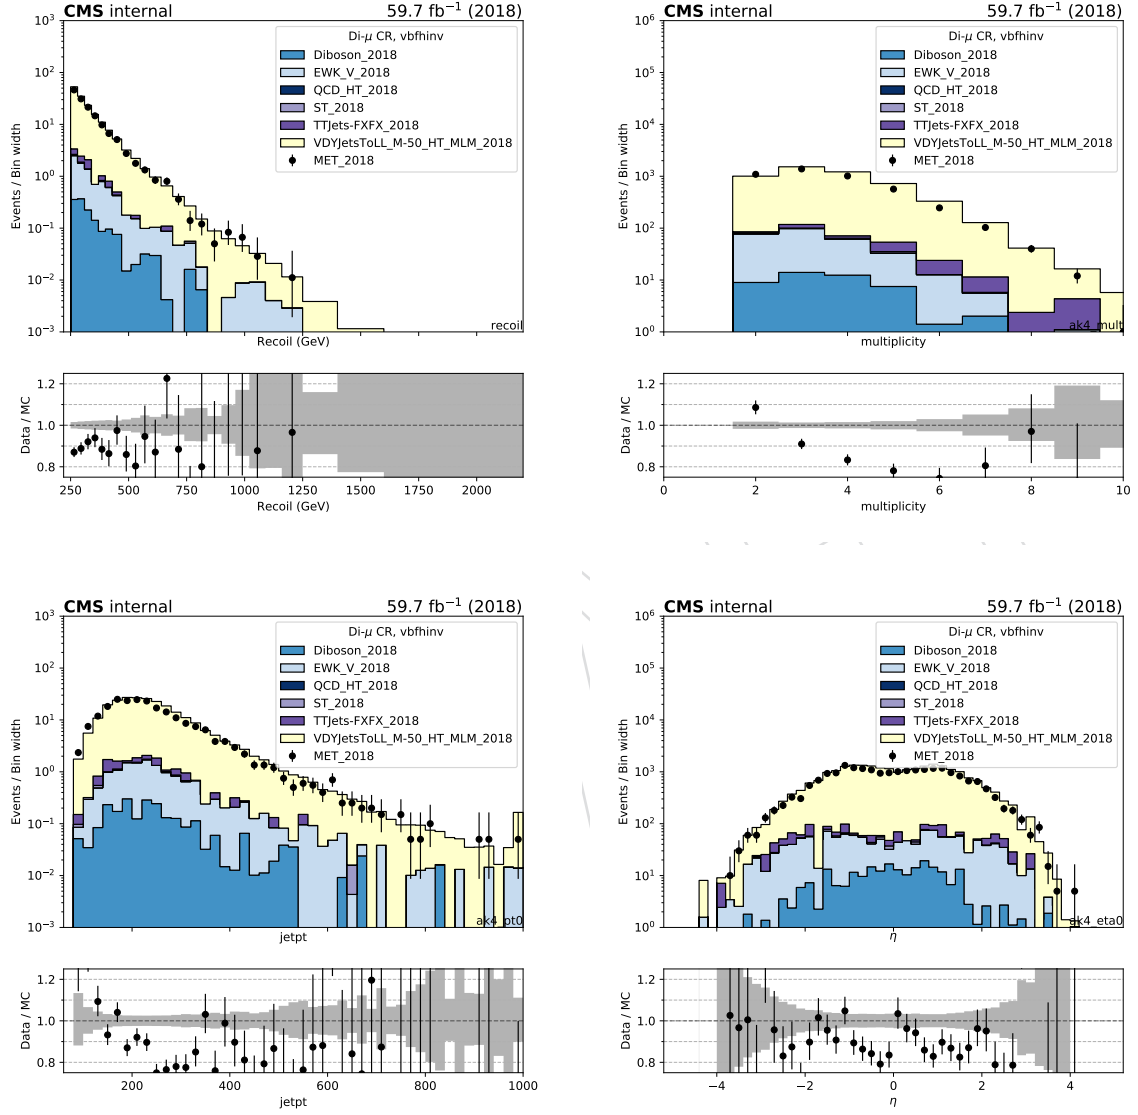

Figure 30: Comparison between 2018 data and Monte Carlo simulation in the double muon control sample for the recoil distribution, the AK4 jet multiplicity distribution, p_T and η distribution of the leading AK4 jet with the VBF selection.

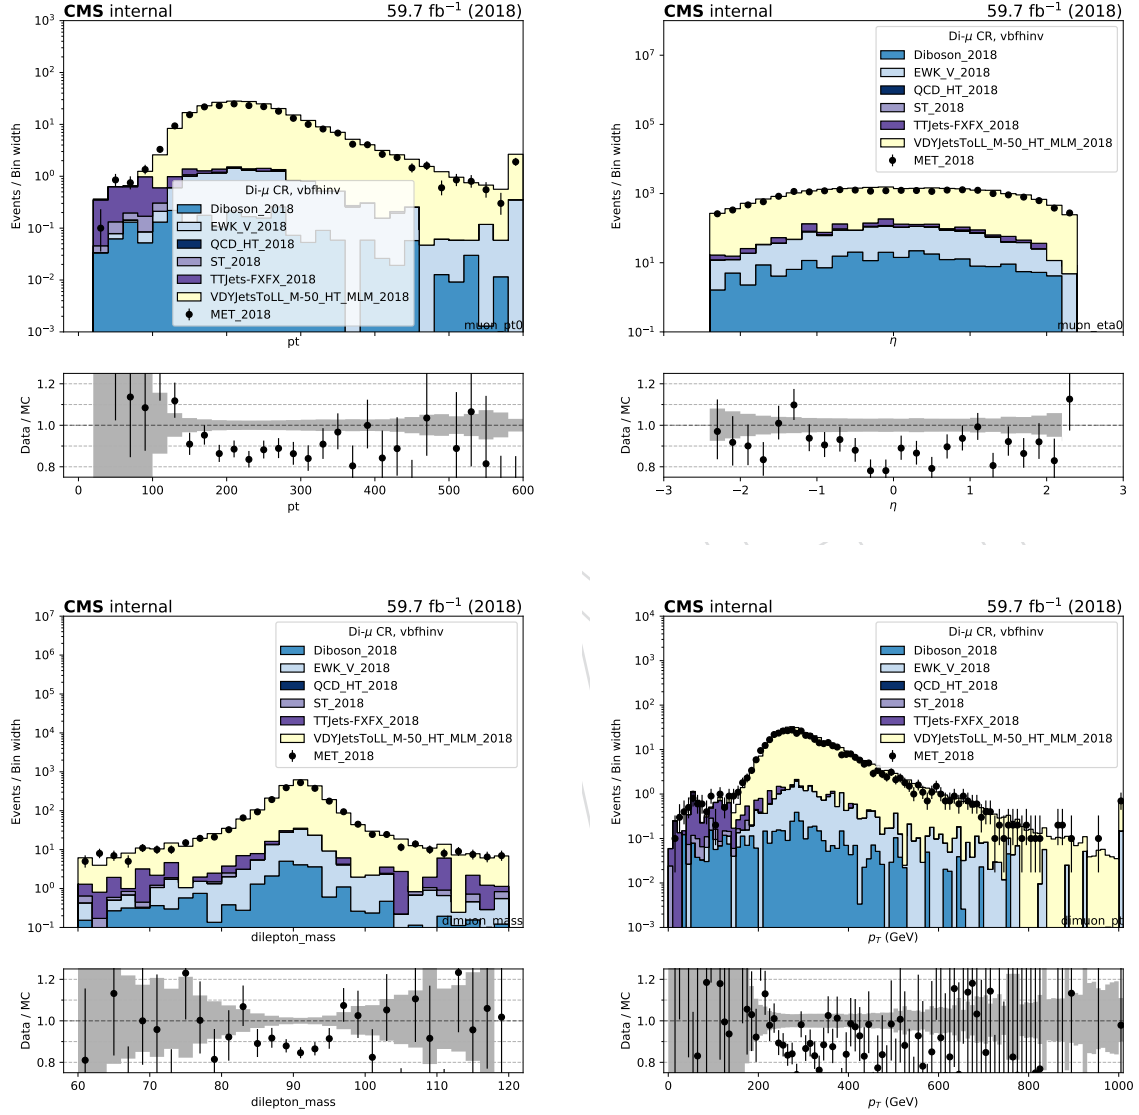

Figure 31: Comparison between 2018 data and monte carlo simulation in the double muon control sample for the p_T and η of the leading muon and the transverse mass and p_T of the dimuon candidate with the VBF selection.

Events for the double-electron control sample are collected with the single-electron and photon triggers described in Sec. 2. In the offline analysis, events in the dielectron control sample are required to contain exactly two oppositely charged electrons with leading (trailing) electron p_T greater than 40 (10) GeV, with at least one of the two passing the tight candidate definition. The SR p_T^{miss} requirement is replacement an identical requirement on the hadronic recoil, which is defined as the sum of \vec{p}_T^{miss} and the muon \vec{p}_T , and thus corresponds to the distribution of the Z p_T smeared with the p_T^{miss} resolution. Similar to the dimuon control sample case, the invariant mass of the dielectron system is required to be between 60 and 120 GeV to be consistent with a Z boson decay.

Figs. 32 and 34 shows the distributions of the recoil, the number of jets, and the p_T and η distribution of the leading AK4 jet for events in the double-electron control sample for the monojet category in 2017 and 2018 datasets, respectively. Figs. ?? and ?? show the distributions of the leading electron p_T and η , as well as the dielectron mass and p_T , again for 2017 and 2018, respectively.

DRAFT

Figure 32: Comparison between 2017 data and monte carlo simulation in the double electron control sample for the recoil distribution, the AK4 jet multiplicity distribution, p_T and η distribution of the leading AK4 jet with the monojet selection.

Figure 34: Comparison between 2018 data and monte carlo simulation in the double electron control sample for the recoil distribution, the AK4 jet multiplicity distribution, p_T and η distribution of the leading AK4 jet with the monojet selection.

Figure 35: Comparison between 2018 data and monte carlo simulation in the double electron control sample for the p_T and η of the leading electron and the transverse mass and p_T of the dielectron candidate with the monojet selection.

The $\gamma + \text{jets}$ control sample is selected using events with one high- p_T photon collected using single-photon triggers with p_T thresholds of 165 or 175 GeV, depending on the data taking conditions. The photon is required to have $p_T > 175$ GeV and to pass tight identification and isolation criteria, to ensure a high trigger efficiency of 98%.

Figs. 36 and 36 show the distributions of the recoil, the number of jets, p_T and η distribution of the leading AK4 jet for events in the photon control sample for the monojet category in the 2017 and 2018 datasets, respectively. Similarly, Figs. 37 and 39 show the distributions of the photon p_T and η .

Figure 39: Comparison between 2018 data and monte carlo simulation in the photon control sample for the p_T and η of the leading photon with the monojet selection.

The largest background contributions, from $Z(\nu\nu) + \text{jets}$ and $W(\ell\nu) + \text{jets}$ processes, are estimated using data from five mutually exclusive control samples selected from dimuon, dielectron, single-muon, single-electron, and $\gamma + \text{jets}$ final states as explained below. The hadronic recoil p_T is used as a proxy for p_T^{miss} in these control samples, and is defined by excluding identified leptons or photons from the p_T^{miss} calculation.

The remaining backgrounds that contribute to the total event yield in the signal region are much smaller than those from $W(\ell\nu) + \text{jets}$ processes. These smaller backgrounds include QCD multijet events which are measured from data using a $\Delta\phi$ extrapolation method and will be discussed in 6.1, and top quark and diboson processes, which are obtained directly from simulation.

QCD multijet production yields transversely well-balanced events. However, due to jet energy mismeasurements, uninstrumented or non-functional detector regions, or neutrinos from semileptonic decays of heavy-flavour mesons; the balance might no longer be preserved yielding a final state with E_T^{miss} . Although such effects are rare, due to large QCD production cross section such QCD multijet events can show up in final states with large E_T^{miss} . In this analysis, event selection is constructed to suppress contributions from such events to below percent level (0.02%) of the total background. On the other hand, this background is known to be badly reproduced in simulation, therefore, we employed a data driven prediction for this process to be used in the final simultaneous fit.

For this measurement the ABCD method is employed using the $\min \Delta\phi(\text{jet}, E_T^{\text{miss}})$ and E_T^{miss} variables. $\min \Delta\phi(\text{jet}, E_T^{\text{miss}})$ variable gives a strong handle on QCD multijet events since the jet momentum mismeasurements yielding large E_T^{miss} will also naturally yield low separation in ϕ between these objects.

The distribution of $\min \Delta\phi(\text{jet}, E_T^{\text{miss}})$ without imposing any selection on this variable after signal region event selection is shown in Fig. 40.

Large amounts of QCD multijet events are found at low $\min \Delta\phi(\text{jet}, E_T^{\text{miss}})$ region. As a result, the selection for the A, B, C and D regions are determined to be as follows:

- Region A: $E_T^{\text{miss}} \leq 250$ and $\min \Delta\phi(\text{jet}, E_T^{\text{miss}}) \leq 0.5$
- Region B: $E_T^{\text{miss}} > 250$ and $\min \Delta\phi(\text{jet}, E_T^{\text{miss}}) \leq 0.5$
- Region C: $E_T^{\text{miss}} \leq 250$ and $\min \Delta\phi(\text{jet}, E_T^{\text{miss}}) > 0.5$
- Region D: $E_T^{\text{miss}} > 250$ and $\min \Delta\phi(\text{jet}, E_T^{\text{miss}}) > 0.5$

The E_T^{miss} distribution split in regions for the QCD multijet simulation is shown in Fig. 41. Each contribution from each of the regions specified above is shown with a different color. The two dimensional distribution of the $\min \Delta\phi(\text{jet}, E_T^{\text{miss}})$ vs E_T^{miss} for QCD multijet simulation is also shown.

The ratio between the regions of low and high $\min \Delta\phi(\text{jet}, E_T^{\text{miss}})$ then computed as:

$$r = \frac{\min \Delta\phi(\text{jet}, E_T^{\text{miss}}) > 0.5}{\min \Delta\phi(\text{jet}, E_T^{\text{miss}}) < 0.5}$$

This ratio computed using the QCD multijet simulation is shown in Fig. 6.1 and is fitted by a double exponential function. It has been shown in earlier studies [?] that the shape difference

Figure 40: The distribution of $\min \Delta\phi(\text{jet}, E_T^{\text{miss}})$ without imposing any selection on this variable

in this ratio at different E_T^{miss} regions arises from threshold effects, pileup at lower E_T^{miss} values, where as at higher values, gaussian core of the jet energy resolution dictates the shape and various over and under measurements of the jet energies could morph the exponential shape. This is the reason why this ratio is fitted by a double exponential.

The data-driven estimation starts by taking the events from region B defined by $E_T^{\text{miss}} > 250$ and $\min \Delta\phi(\text{jet}, E_T^{\text{miss}}) \leq 0.5$ selections after imposing the full event selection in MET dataset. All other backgrounds corresponding to V+jets processes are subtracted from these selected events. The remaining events are scaled by the double exponential function fitted to the ratio as shown in Fig. 42. The systematic uncertainty sources are also studied. The largest source of uncertainty in the measurement is due to the variations of jet energy scale, resolution and the fit. To estimate the effect of this variation in the measurment, the jet energy scale and resolution is varied up and down by 1σ and the above procedure is repeated. The corresponding variations in the ratio are treated as the systematic uncertainty. The total uncertainty is found to vary from 20% to 150% as a function of E_T^{miss} and is shown in Fig. 42 as well. The largest deviation in each bin is taken as the uncertainty.

The final estimation including the uncertainties and the comparison of the final estimation to those estimations coming from the simulated events is shown in Fig. 6.1.

Figure 41: The E_T^{miss} distribution split in regions for the QCD multijet simulation. Each contribution from each of the regions specified above is shown with a different color.

A binned likelihood fit to the data as presented in Ref. [?] is performed simultaneously in the five different control samples and in the signal region, for events selected in both the monojet and mono-V categories, to estimate the $Z(\nu\nu) + \text{jets}$ and $W(\ell\nu) + \text{jets}$ rate in each p_T^{miss} bin. The full likelihood can be seen below:

$$\begin{aligned}
\mathcal{L}_c(\mu^{Z \rightarrow \nu\nu}, \mu, \theta) = & \prod_i \text{Poisson} \left(d_i^\gamma | B_i^\gamma(\theta) + \frac{\mu_i^{Z \rightarrow \nu\nu}}{R_i^\gamma(\theta)} \right) \\
& \times \prod_i \text{Poisson} \left(d_i^Z | B_i^Z(\theta) + \frac{\mu_i^{Z \rightarrow \nu\nu}}{R_i^Z(\theta)} \right) \\
& \times \prod_i \text{Poisson} \left(d_i^W | B_i^W(\theta) + \frac{f_i(\theta) \mu_i^{Z \rightarrow \nu\nu}}{R_i^W(\theta)} \right) \\
& \times \prod_i \text{Poisson} \left(d_i | B_i(\theta) + (1 + f_i(\theta)) \mu_i^{Z \rightarrow \nu\nu} + \mu S_i(\theta) \right)
\end{aligned} \tag{4}$$

In the above likelihood, $d_i^{\gamma/Z/W}$ are the observed number of events in each bin of the photon, dimuon/dielectron and single-muon/single-electron control regions, and $B_i^{\gamma/Z/W}$ is the background in the respective control regions. The systematic uncertainties (θ) enter the likelihood as additive perturbations to the transfer factors $R_i^{\gamma/Z/W}$, and are modeled as Gaussians. The parameter $\mu^{Z \rightarrow \nu\nu}$ represents the yield of the $Z \rightarrow \nu\nu$ background in the signal region, and is left freely floating in the fit. The function $f_i(\theta)$ is the transfer factor between the $Z \rightarrow \nu\nu$ and $W + \text{jets}$ backgrounds in the signal region and represents a constraint between these backgrounds. The likelihood also includes the signal region with B_i representing all the backgrounds, S representing the nominal signal prediction, and μ being the signal strength parameter also left floating in the fit.

Figure 42: The distribution and the fit on the ratio is shown on the top. The distributions and the fits for the up and down variations are shown on the bottom left and right, respectively.

In this likelihood, the expected numbers of $Z(\nu\nu) + \text{jets}$ events in each bin of p_T^{miss} are the free parameters of the fit. Transfer factors, derived from simulation, are used to link the yields of the $Z(\ell\ell) + \text{jets}$, $W(\ell\nu) + \text{jets}$ and $\gamma + \text{jets}$ processes in the control regions with the $Z(\nu\nu) + \text{jets}$ and $W(\ell\nu) + \text{jets}$ background estimates in the signal region. These transfer factors are defined as the ratio of expected yields of the target process in the signal region and the process being measured in the control sample.

To estimate the $W(\ell\nu) + \text{jets}$ background in the signal region, the transfer factors between the $W(\mu\nu) + \text{jets}$ and $W(e\nu) + \text{jets}$ event yields in the single-lepton control samples and the estimates of the $W(\ell\nu) + \text{jets}$ background in the signal region are constructed. These transfer factors take into account the impact of lepton acceptances and efficiencies, lepton veto efficiencies, and the difference in the trigger efficiencies in the case of the single-electron control sample.

Figure 43: The data driven estimation of multijet events using the fit is compared to the yields obtained by simulation is shown on the left.

The distribution on the right row show the central estimation with the associated uncertainties coming from the systematic fits. The ratio pad shows the % uncertainty per bin.

The $Z \rightarrow \nu\nu$ background prediction in the signal region is connected to the yields of $Z \rightarrow \mu^+\mu^-$ and $Z \rightarrow e^+e^-$ events in the dilepton control samples. The associated transfer factors account for the differences in the branching ratio of Z bosons to charged leptons relative to neutrinos and the impact of lepton acceptance and selection efficiencies. In the case of dielectron events, the transfer factor also takes into account the difference in the trigger efficiencies. The resulting constraint on the $Z(\nu\nu) + \text{jets}$ process from the dilepton control samples is limited by the statistical uncertainty in the dilepton control samples because of the large difference in branching fractions between Z boson decays to neutrinos and Z boson decays to muons and electrons.

The $\gamma + \text{jets}$ control sample is also used to predict the $Z(\nu\nu) + \text{jets}$ process in the signal region through a transfer factor, which accounts for the difference in the cross sections of the $\gamma + \text{jets}$ and $Z(\nu\nu) + \text{jets}$ processes, the effect of acceptance and efficiency of identifying photons along with the difference in the efficiencies of the photon and p_T^{miss} triggers. The addition of the $\gamma + \text{jets}$ control sample mitigates the impact of the limited statistical power of the dilepton constraint, because of the larger production cross section of $\gamma + \text{jets}$ process compared to that of $Z(\nu\nu) + \text{jets}$ process.

Finally, a transfer factor is also defined to connect the $Z(\nu\nu) + \text{jets}$ and $W(\ell\nu) + \text{jets}$ background yields in the signal region, to further benefit from the larger statistical power that the $W(\ell\nu) + \text{jets}$ background provides, making it possible to experimentally constrain $Z(\nu\nu) + \text{jets}$ production at high p_T^{miss} .

These transfer factors rely on an accurate prediction of the ratio of Z + jets, W + jets, and $\gamma + \text{jets}$ cross sections. Therefore, LO simulations for these processes are corrected using boson p_T -dependent NLO QCD K-factors derived using MADGRAPH5_aMC@NLO. They are also corrected using p_T -dependent higher-order EW corrections extracted from theoretical calculations [? ? ? ? ? ?]. The higher-order corrections are found to improve the data-to-

simulation agreement for both the absolute prediction of the individual $Z + \text{jets}$, $W + \text{jets}$, and $\gamma + \text{jets}$ processes, and their respective ratios. All transfer factors are shown in Fig 44 45 46.

Figure 44: Transfer factors for the $Z \rightarrow \nu\nu$ background as a function of the recoil using the dimuon, dielectron control regions in monojet (left) and mono-V (right) final state. The orange band shows the theoretical uncertainties on the ratios.

The remaining backgrounds that contribute to the total event yield in the signal region are much smaller than those from $Z(\nu\nu) + \text{jets}$ and $W(\ell\nu) + \text{jets}$ processes. These smaller backgrounds include QCD multijet events which are measured from data using a $\Delta\phi$ extrapolation method [? ?], and top quark and diboson processes, which are obtained directly from simulation.

Figure 45: Transfer factors for the to estimate the $Z \rightarrow \nu\nu$ background from photon control region and W+jets in the signal region as a function of the recoil for the monojet (left) and mono-V (right) final state.

Figure 46: Transfer factors for the $W(\ell\nu) + \text{jets}$ background as a function of the recoil using the singlemuon, singleelectron control regions in monojet (left) and mono-V (right) final state. The orange band shows the theoretical uncertainties on the ratios.

Systematic uncertainty discussion is divided into sections separating out the uncertainties in the transfer factors from the ones in the MC based backgrounds.

Systematic uncertainties in the transfer factors are modeled as constrained nuisance parameters and include both experimental and theoretical uncertainties in the $\gamma + \text{jets}$ to $Z + \text{jets}$ and $W + \text{jets}$ to $Z + \text{jets}$ differential cross section ratios.

Theoretical uncertainties in V-jets and $\gamma + \text{jets}$ processes include effects from QCD and EW higher-order corrections along with PDF modeling uncertainty. To estimate the theoretical uncertainty in the V-jets and $\gamma + \text{jets}$ ratios due to QCD and EW higher-order effects as well as their correlations across the processes and p_T bins, the recommendations of Ref. [?] are employed, as detailed in the following explanation.

Three separate sources of uncertainty associated with QCD higher order corrections are used. One of the uncertainties considered comes from the variations around the central renormalization and factorization scale choice. It is evaluated by taking the differences in the NLO cross section as a function of boson p_T after changing the renormalization and factorization scales by a factor of two and a factor of one-half with respect to the default value. These constant scale variations mainly affect the overall normalization of the boson p_T distributions and therefore underestimate the shape uncertainties that play an important role in the extrapolation of low- p_T measurements to high- p_T . A second, conservative shape uncertainty derived from altered boson p_T spectra is used to supplement the scale uncertainties and account for the p_T dependence of the uncertainties. The modeling of the correlations between the processes assumes a close similarity of QCD effects between all V-jets and $\gamma + \text{jets}$ processes. However, the QCD effects in $\gamma + \text{jets}$ production could differ compared to the case of $Z + \text{jets}$ and $W + \text{jets}$ productions. In order to account for this variation, a third uncertainty is computed based on the difference of the known QCD K-factors of the $W + \text{jets}$ and $\gamma + \text{jets}$ processes with respect to $Z + \text{jets}$ production. All QCD uncertainties are correlated across the $Z + \text{jets}$, $W + \text{jets}$, $\gamma + \text{jets}$ processes, and also correlated across the bins of the hadronic recoil p_T .

For the V-jets and $\gamma + \text{jets}$ processes, nNLO-EW corrections are applied, which correspond to full NLO EW corrections [?] supplemented by two-loop Sudakov EW logarithms [?]. We also considered three separate sources of uncertainty arising from the following: pure EW higher-order corrections failing to cover the effects of unknown Sudakov logarithms in the perturbative expansion beyond NNLO, missing NNLO effects that are not included in the nNLO EW calculations, and the difference between the next-to-leading logarithmic (NLL) Sudakov approximation at two-loop and simple exponentiation of the full NLO EW correction. The variations due to the effect of unknown Sudakov logs are correlated across the $Z + \text{jets}$, $W + \text{jets}$, and $\gamma + \text{jets}$ processes and are also correlated across the bins of hadronic recoil p_T . On the other hand, the other two sources of EW uncertainties are treated as uncorrelated across the V-jet and $\gamma + \text{jets}$ processes, and an independent nuisance parameter is used for each process.

A recommendation that includes a factorized approach to partially include mixed QCD-EW corrections is outlined in Ref. [?]. An additional uncertainty is introduced to account for the difference between the corrections done in the multiplicative and the additive approaches, to account for the non-factorized mixed EW-QCD effects.

The summary of the aforementioned theoretical uncertainties including their magnitude and correlation is outlined in Table 9.

Table 9: Theoretical uncertainties considered in the V-jets and $\gamma + \text{jets}$ processes, and their ratios. The correlation between each process and between the p_T bins are described.

Uncertainty source	Process (magnitude)	Correlation
Fact. & renorm. scales (QCD)	$Z \rightarrow \nu\nu/W \rightarrow \ell\nu$ (0.1 – 0.5%) $Z \rightarrow \nu\nu/\gamma + \text{jets}$ (0.2 – 0.5%)	Correlated between processes; and in p_T
p_T shape dependence (QCD)	$Z \rightarrow \nu\nu/W \rightarrow \ell\nu$ (0.4 – 0.1%) $Z \rightarrow \nu\nu/\gamma + \text{jets}$ (0.1 – 0.2%)	Correlated between processes; and in p_T
Process dependence (QCD)	$Z \rightarrow \nu\nu/W \rightarrow \ell\nu$ (0.4 – 1.5%) $Z \rightarrow \nu\nu/\gamma + \text{jets}$ (1.5 – 3.0%)	Correlated between processes; and in p_T
Effects of unknown Sudakov logs (EW)	$Z \rightarrow \nu\nu/W \rightarrow \ell\nu$ (0 – 0.5%) $Z \rightarrow \nu\nu/\gamma + \text{jets}$ (0.1 – 1.5%)	Correlated between processes; and in p_T
Missing NNLO effects (EW)	$Z \rightarrow \nu\nu$ (0.2 – 3.0%) $W \rightarrow \ell\nu$ (0.4 – 4.5%) $\gamma + \text{jets}$ (0.1 – 1.0%)	Uncorrelated between processes; correlated in p_T
Effects of NLL Sudakov approx. (EW)	$Z \rightarrow \nu\nu$ (0.2 – 4.0%) $W \rightarrow \ell\nu$ (0 – 1.0%) $\gamma + \text{jets}$ (0.1 – 3.0%)	Uncorrelated between processes; correlated in p_T
Unfactorized mixed QCD-EW corrections	$Z \rightarrow \nu\nu/W \rightarrow \ell\nu$ (0.15 – 0.3%) $Z \rightarrow \nu\nu/\gamma + \text{jets}$ (<0.1%)	Correlated between processes; and in p_T
PDF	$Z \rightarrow \nu\nu/W \rightarrow \ell\nu$ (0 – 0.3%) $Z \rightarrow \nu\nu/\gamma + \text{jets}$ (0 – 0.6%)	Correlated between processes; and in p_T

Experimental uncertainties including the reconstruction efficiency (1% per muon or electron) and the selection efficiencies of leptons (1% per muon and 2% per electron), photons (2%), and hadronically decaying τ leptons (5%), are also incorporated. Uncertainties in the purity of photons in the $\gamma + \text{jets}$ control sample (2%), and in the efficiency of the electron (2%), photon (2%), and p_T^{miss} (1–4%) triggers, are included and are fully correlated across all the bins of hadronic recoil p_T and p_T^{miss} . The uncertainty in the efficiency of the b jet veto is estimated to be 6% (2)% for the contribution of the top quark (diboson) background.

In addition, the lepton veto uncertainties are also included in the transfer factors and are estimated through propagating the overall uncertainty on the tagging scale factor (loose-muon ID, veto-electron ID and loose MVA-tau ID) into the vetoed selection based on the flavour composition of the $W + \text{jets}$ process. The resulting uncertainties are shown in Fig. 47(b). These uncertainties are only applicable to the leptons in the signal region that are in acceptance and not rejected by the lepton veto. The fraction of each flavor of the leptons both in and out of acceptance are shown in Fig. 48. The overall magnitude of the lepton-veto uncertainty is found to be around 1 (2)% and is found to be dominated by the τ -veto uncertainty.

The uncertainty in the efficiency of the V tagging requirements is estimated to be 9% in the mono-V category. The uncertainty in the modeling of p_T^{miss} in simulation [?] is estimated to be 4% and is dominated by the uncertainty in the jet energy scale.

The full list of uncertainties on the transfer factors are summarized in Table 10. It should be noted that uncertainties that are common both in the denominator and the numerator of these transfer factors, such as jet energy scale, jet energy resolution, luminosity do not contribute to the total uncertainty as they cancel out in the ratio.

Figure 47: PDF uncertainty and veto uncertainty

Figure 48: The hadronic τ lepton contribution is shown with dotted (solid) blue lines for in (out) of acceptance leptons, where as electron contribution is shown with green, and muon with orange lines for the Wjets background in the signal region after the lepton vetos.

Uncertainties assigned to the simulation based processes include the uncertainty in the efficiency of the b-jet veto and is estimated to be 3(1)% for the top quark (diboson) background. A systematic uncertainty of 10% is included for the top quark background normalization due to the modeling of the top quark p_T distribution in simulation. Systematic uncertainties of 10% and 20% are included in the normalizations of the top quark [?] and diboson backgrounds [? ?], respectively, to account for the uncertainties in their cross sections in the relevant kinematic phase space. Lastly, the uncertainty in the QCD multijet background estimate is found to be

Table 10: Experimental uncertainties affecting transfer factors used in the analysis to estimate $W \rightarrow \ell\nu$ background in the signal region.

Source	Process	Uncertainty
Electron trigger	$W_{\text{SR}}/W_{e\nu}$	1%
$E_{\text{T}}^{\text{miss}}$ trigger	$W_{\text{SR}}/W_{e(\mu)\nu}$	2% (shape)
Muon-reco efficiency	$W_{\text{SR}}/W_{\mu\nu}$	1%
Muon-ID efficiency	$W_{\text{SR}}/W_{\mu\nu}$	1%
Electron-reco efficiency	$W_{\text{SR}}/W_{e\nu}$	1%
Electron-ID efficiency	$W_{\text{SR}}/W_{e\nu}$	1.5%
Muon veto	$W_{\text{SR}}/W_{e(\mu)\nu}$	< 1% (shape)
Electron veto	$W_{\text{SR}}/W_{e(\mu)\nu}$	< 1% (shape)
Tau veto	$W_{\text{SR}}/W_{e(\mu)\nu}$	2% (shape)
PDF	$W_{\text{SR}}/W_{e(\mu)\nu}$	2% (shape)

between 50–150% due to the variations of the jet response and the statistical uncertainty of the extrapolation factors. All the above mentioned uncertainties are summarized in Table 11.

Table 11: Uncertainties assigned to the simulation based processes.

Source	Process	Uncertainty
Luminosity	All processes	2.3%
Electron trigger	All processes in single-electron CR	1%
$E_{\text{T}}^{\text{miss}}$ trigger	All processes in signal region and single-muon CR	2%
Jet/ $E_{\text{T}}^{\text{miss}}$ energy scale	All processes	4%
Pileup	All processes	2% (shape)
Muon-reco efficiency	All processes in single-muon CR	1%
Muon-ID efficiency	All processes in single-electron CR	1%
Electron-reco efficiency	All processes in single-electron CR	1%
Electron-ID efficiency	All processes in single-electron CR	1.5%
b-jet veto	Top in SR and all CRs	3%
	All remaining in SR and all CRs	1%
Top p_{T} reweight	Top	10%
Top norm	Top	10%
VV norm	VV	15%
$Z(\ell\ell) + \text{jets}$ norm	$Z(\ell\ell) + \text{jets}$ (SR)	20%
	in SR	50-100% (shape)
Fake muons	in $W_{\mu\nu}$	50%
Fake electrons	in $W_{e\nu}$	50%

An important cross-check of the application of p_T -dependent NLO QCD and EW corrections is represented by the agreement between data and simulation in the ratio of $Z + \text{jet}$ events to both $\gamma + \text{jet}$ events and $W + \text{jet}$ events in the control samples, as a function of hadronic recoil p_T .

Figure ?? shows the ratio between $Z(\ell\ell) + \text{jets}$ and $\gamma + \text{jets}$ (left), $Z(\ell\ell) + \text{jets}$ and $W(\ell\nu) + \text{jets}$ (middle), and the one between $W(\ell\nu) + \text{jets}/\gamma + \text{jets}$ processes (right) as a function of the recoil for events selected in the monojet category. While we do not explicitly use a $W(\ell\nu) + \text{jets}/\gamma + \text{jets}$ constraint in the analysis, the two cross sections are connected through the $Z + \text{jets}/\gamma + \text{jets}$ and $Z + \text{jets}/W + \text{jets}$ constraints. Therefore, it is instructive to examine the data-MC comparison of the $W(\ell\nu) + \text{jets}/\gamma + \text{jets}$ ratio. Good agreement is observed between data and simulation after the application of the NLO corrections as shown in Fig. 49 and Fig. 50 for 2017 and 2018 data respectively.

Figures 51–53 show the results of the combined fit in all control samples and the signal region. Data in the control samples are compared to the pre-fit predictions from simulation and the post-fit estimates obtained after performing the fit. The control samples with larger yields dominate the fit results. A normalization difference of 7% is observed in the pre-fit distributions for the mono-V category in the single-lepton and dilepton control regions. The sources of the differences are identified to be the modeling of the pruned mass variable and the large theoretical uncertainties in the diboson and top quark backgrounds, which are the leading backgrounds in these regions. The normalization difference is found to be fully mitigated by the fitting procedure.

Figure 49: Comparison between 2017 data and MC simulation for the $Z(\ell\ell)/\gamma + \text{jets}$, $Z(\ell\ell)/W(\ell\nu)$, and $W(\ell\nu)/\gamma + \text{jets}$ ratios as a function of the hadronic recoil in the monojet category. In the lower panels, ratios of data with the pre-fit background prediction are shown. The gray bands include both the pre-fit systematic uncertainties and the statistical uncertainty in the simulation.

Figure 50: Comparison between 2018 data and MC simulation for the $Z(\ell\ell)/\gamma + \text{jets}$, $Z(\ell\ell)/W(\ell\nu)$, and $W(\ell\nu)/\gamma + \text{jets}$ ratios as a function of the hadronic recoil in the monojet category. In the lower panels, ratios of data with the pre-fit background prediction are shown. The gray bands include both the pre-fit systematic uncertainties and the statistical uncertainty in the simulation.

Figure 51: Comparison between data and MC simulation in the $\gamma + \text{jets}$ control sample before and after performing the simultaneous fit across all the control samples and the signal region assuming the absence of any signal. The left plot shows the monojet category and the right plot shows the mono-V category. The hadronic recoil p_T in $\gamma + \text{jetsevents}$ is used as a proxy for p_T^{miss} in the signal region. The last bin includes all events with hadronic recoil p_T larger than 1250 (750) GeV in the monojet (mono-V) category. In the lower panels, ratios of data with the pre-fit background prediction (red open points) and post-fit background prediction (blue full points) are shown for both the monojet and mono-V categories. The gray band in the lower panel indicates the post-fit uncertainty after combining all the systematic uncertainties. Finally, the distribution of the pulls, defined as the difference between data and the post-fit background prediction relative to the quadrature sum of the post-fit uncertainty in the prediction and statistical uncertainty in data, is shown in the lowest panel.

Figure 52: Comparison between data and MC simulation in the dimuon (upper row) and di-electron (lower row) control samples before and after performing the simultaneous fit across all the control samples and the signal region assuming the absence of any signal. Plots correspond to the monojet (left) and mono-V (right) categories, respectively, in the dilepton control sample. The hadronic recoil p_T in dilepton events is used as a proxy for p_T^{miss} in the signal region. The other backgrounds include top quark, diboson, and $W + \text{jets}$ processes. The description of the lower panels is the same as in Fig. 51.

Figure 53: Comparison between data and MC simulation in the single-muon (upper row) and single-electron (lower row) control samples before and after performing the simultaneous fit across all the control samples and the signal region assuming the absence of any signal. Plots correspond to the monojet (left) and mono-V (right) categories, respectively, in the single-lepton control samples. The hadronic recoil p_T in single-lepton events is used as a proxy for p_T^{miss} in the signal region. The other backgrounds include top quark, diboson, and QCD multijet processes. The description of the lower panels is the same as in Fig. 51.
